Paper under double-blind review

### **ABSTRACT**

Modeling event sequences of multiple event types with marked temporal point processes (MTPPs) provides a principled way to uncover governing dynamical rules and predict future events. Current neural network approaches to MTPP inference rely on training separate, specialized models for each target system. We pursue a radically different approach: drawing on amortized inference and in-context learning, we pretrain a deep neural network to infer, *in-context*, the conditional intensity functions of event histories from a context defined by sets of event sequences. Pretraining is performed on a large synthetic dataset of MTPPs sampled from a broad distribution of Hawkes processes. Once pretrained, our Foundation Inference Model for Point Processes (FIM-PP) can estimate MTPPs from realworld data without any additional training, or be rapidly finetuned to target systems. Experiments show that this amortized approach matches the performance of specialized models on next-event prediction across common benchmark datasets. We provide the pretrained model weights with the supplementary material.

#### 1 Introduction

The mathematical modeling of asynchronous and irregular sequences of events has long occupied a distinctive role in the machine learning community. Temporal point processes comprise the canonical framework for modeling neural dynamics (Truccolo et al., 2005; Linderman & Adams, 2014), and serve as the de facto tool for describing a wide range of internet phenomena, including retweeting, posting, and information cascades (Zhao et al., 2015; Cvejoski et al., 2020). Their ability to encode fine-grained temporal structure, together with their capacity to reveal causal interactions between events in an interpretable manner, has made them indispensable not only in neuroscience and social media, but also in finance (Aït-Sahalia et al., 2015) and epidemiology Chiang et al. (2022). Despite this centrality, the trajectory of foundation models has developed along a different path. Large-scale pretraining first emerged in natural language processing, enabled by massive internet corpora, and has only recently been extended to dynamical systems, with recent work addressing ODEs (d'Ascoli et al., 2024; Seifner et al., 2025b), MJPs (Berghaus et al., 2025), SDEs (Seifner et al., 2025a), and even specific applications to pharmacology (Marin et al., 2025). It is therefore ironic that event data — the very modality underlying the internet activity that made text-based pretraining possible — has not yet given rise to a corresponding foundation model for point processes. The present work takes a first step toward filling this gap by developing a foundation model explicitly designed for temporal point processes.

Marked Temporal Point Processes (MTPPs) (Daley & Vere-Jones, 2007; Rasmussen, 2018) are stochastic processes consisting of ordered occurrence times, each accompanied by a categorical mark specifying its type. Formally, the objective is to specify the conditional distribution of the next event time and mark, given the history of the process up to the current time. The extensive literature on point processes explores different ways to encode event histories and to specify the stochastic mechanism that governs new arrivals and their marks (Lin et al., 2024). A common approach is to represent this distribution through a conditional intensity function, which describes the instantaneous rate at which events of different types occur given the history. Traditionally, models such as the Hawkes process (Hawkes, 1971) define this conditional intensity as the superposition of self-exciting effects from past events. Forecasting is then carried out recurrently using Ogata's

<sup>&</sup>lt;sup>1</sup>Model and data: https://anonymous.4open.science/r/FIM-PP-0303/README.md

thinning algorithm applied to the conditional intensity. Building on this cornerstone, more recent work has extended Hawkes processes by parameterizing event histories with neural architectures (Mei & Eisner, 2017), including recurrent neural networks (Du et al., 2016), attention mechanisms (Zhang et al., 2020), and Transformers (Zuo et al., 2021). These models are typically trained either via maximum likelihood — often requiring expensive integral evaluations — or through generative approaches that bypass intensity modeling altogether and directly sample future events conditional on the past (Kerrigan et al., 2024; Zeng et al., 2024). A fundamental limitation of these approaches is their lack of transferability: each new dataset requires retraining from scratch, forcing the model to relearn representations for every distinct dynamics.

In contrast, modern approaches to dynamical systems increasingly prioritize *pretraining on synthetic data*, yielding general models that can learn dynamics *in-context*. This paradigm has the crucial advantage that practitioners no longer need to train models *de novo* for every dataset, but can instead obtain accurate characterizations in a *zero-shot* manner. Within this family, two variants have emerged: Prior-fitted Networks (PFNs) and Foundation Inference Models (FIMs). PFNs train networks to approximate *predictive posterior distributions* in a sequence-to-sequence or context-to-sequence fashion, often implemented with recurrent or transformer architectures (Müller et al., 2022; Hollmann et al., 2022; Müller et al., 2025). FIMs, by contrast, focus on directly *estimating the infinitesimal operators* of stochastic processes (e.g., drift and diffusion functions for SDEs), thereby retaining a degree of interpretability (Berghaus et al., 2025; Seifner et al., 2025a;b). Access to these operators enables explicit study of physically relevant observables such as entropy production, stationary distributions, and attractors.

In the context of point processes, we adapt the FIM pretraining paradigm to MTPPs by following three steps. First, we define a broad family of conditional intensity functions, inducing a diverse prior over MTPPs. This prior captures assumptions about the excitatory and inhibitory effects between events, as well as the interaction structure across event types. Second, we sample MTPPs from this prior, generate synthetic event sequences, and construct training pairs of event histories with their corresponding intensities, creating a meta-learning task that amortizes inference across heterogeneous dynamics. Third, we train a neural network to recover conditional intensities from observed histories. A key advantage of this formulation is that it preserves the possibility of injecting *expert knowledge*: the choice of prior directly encodes desired inductive biases, guiding the network toward desired dynamical models. We summarize our contributions:

- 1. Introduce a synthetic data generation framework for sampling event sequences from a *prior distribution over Hawkes processes*, with randomized base intensities, kernels, and interaction types (excitatory, inhibitory, neutral). We empirically demonstrate that this construction encodes a strong prior, enabling models trained on it to *generalize* across both in-distribution processes and real-world event data.
- 2. Train the first transformer-based recognition model capable of estimating *in-context* the conditional intensity functions of *marked temporal point processes*, where history representations serve as queries and the encoded sequence context provides the keys and values.
- 3. Show that the resulting model achieves strong *zero-shot* performance across synthetic benchmarks and multiple real-world datasets, and that it can be *rapidly finetuned on new event data*.

#### 2 Related Work

Here we provide a brief overview of temporal point processes. For detailed surveys and benchmarks of deep TPP models, including open challenges in history encoding, conditional intensity design, relational discovery, and learning strategies, see e.g., Lin et al. (2024) and Xue et al. (2024).

While the mathematical theory of point processes is extensive (Daley & Vere-Jones, 2007; Kingman, 1992), work on temporal point processes (TPPs) in machine learning has crystallized around two central questions: (i) how should representations of past events be constructed, and (ii) how should the future be modeled (Lin et al., 2024). Early approaches, epitomized by the Hawkes process, addressed both questions using linear self-exciting kernels. A natural extension is the neural Hawkes process (Mei & Eisner, 2017), along with related recurrent formulations (Du et al., 2016), which rely on neural representations of past events, trained via likelihood maximization, and model future

events using the thinning algorithm. Later work introduced more expressive architectures. Attention mechanisms (Zuo et al., 2021; Zhang et al., 2020; Yang et al., 2021) extend the memory horizon of TPPs, though at the cost of higher computational demand. Neural ODEs (Chen et al., 2018) have also been incorporated to better capture the irregular timing of events in latent representations (Song et al., 2024; Kidger et al., 2020).

To improve predictive accuracy over long horizons, different decompositions of the likelihood for future arrivals have been proposed (Rasmussen, 2018; Panos, 2024; Deshpande et al., 2021). These works highlight the limitations of intensity-based inference, particularly when relying on thinning algorithms. Such limitations have motivated a shift toward generative models, which typically sample entire sequences. Approaches include optimal transport (Xiao et al., 2017), diffusion models (Zeng et al., 2024; Lüdke et al., 2023), and flow-matching methods (Kerrigan et al., 2024), often trading accuracy for interpretability. In contrast, traditional machine learning methods (Rasmussen, 2013; Malem-Shinitski et al., 2022) emphasize interpretability from the outset. A key advantage of the Hawkes process is that its excitation graph makes causal structure explicit (Xu et al., 2016; Wu et al., 2024), which has been especially relevant in neuroscience (Linderman & Adams, 2014; Truccolo et al., 2005) and in finance, where Hawkes models often serve as hidden drivers of observed activity (Aït-Sahalia et al., 2015). Applications extend more broadly, for instance to dynamics of text (Cvejoski et al., 2020; 2021), social online activity (Zhao et al., 2015) and operations research (Ojeda et al., 2021).

#### 3 Preliminaries

In this section, we recall the definition and basic properties of *marked temporal point processes* (Daley & Vere-Jones, 2007) and *Hawkes processes* (Hawkes, 1971; Laub et al., 2015). Additionally, we define the inference problem our proposed approach tackles.

**Marked Temporal Point Processes:** We consider marked temporal point processes (marked TPPs, or MTPPs) as simple point processes on  $\mathbb{R}_+ \times \mathcal{K}$ , where  $\mathcal{K}$  is a discrete and finite set of marks. The density f of a sequence of events  $\mathcal{S} = \{(t_i, \kappa_i)\}_{i=1}^n$  in the interval [0, T], w.l.o.g. ordered by their time component  $t_i \in \mathbb{R}_+$ , factors into conditional densities

$$f(\{(t_i, \kappa_i\}_{i=1}^n) = \prod_{i=1}^n f((t_i, \kappa_i) \mid \mathcal{H}_{t_i}) = \prod_{i=1}^n f(t_i \mid \mathcal{H}_{t_i}) f(\kappa_i \mid t_i, \mathcal{H}_{t_i}),$$
(1)

where  $\mathcal{H}_t = \{(t_i, \kappa_i) \mid t_i < t\} \subset \mathcal{S}$  is the *history strictly preceding t*. By the last equality of equation 1, MTPPs may be characterized by dependent densities of the *next-event time*  $f(t \mid \mathcal{H}_t)$  and its *event mark*  $f(\kappa \mid t, \mathcal{H}_t)$ . MTPPs are commonly represented by their piece-wise continuous *conditional intensity function* 

$$\lambda(t, \kappa \mid \mathcal{H}_t) = \frac{f(t \mid \mathcal{H}_t)}{1 - \int_{t'}^{t} f(s \mid \mathcal{H}_s) ds} f(\kappa \mid t, \mathcal{H}_t) = \lambda(t \mid \mathcal{H}_t) f(\kappa \mid t, \mathcal{H}_t) , \qquad (2)$$

where t' is the last event time in  $\mathcal{H}_t$ , or t'=0 if  $\mathcal{H}_t=\varnothing$ . The conditional intensity function may be interpreted of the *instantaneous rate* of mark  $\kappa$  occurring at t, conditioned of the history up to time  $t_i$ . Reversely, any such function  $\lambda$ , satisfying some mild conditions, defines the density of an MTPP on a set of events in an interval [0,T] by

$$f\left(\left\{\left(t_{i}, \kappa_{i}\right\}_{i=1}^{n}\right) = \left[\prod_{i=1}^{n} \lambda(t_{i}, \kappa_{i} \mid \mathcal{H}_{t_{i}})\right] \exp\left(-\int_{0}^{T} \lambda(s \mid \mathcal{H}_{s}) ds\right). \tag{3}$$

**Collection of TPPs:** A TPP is just an MTPP with a single mark. An MTPP can be viewed as a *collection of TPPs* per mark, interdependent through a *joined history*. Indeed, given an MTPP as above, the conditional intensity  $\lambda_{\kappa}(t \mid \mathcal{H}_t) = \lambda(t \mid \mathcal{H}_t)f(\kappa \mid t, \mathcal{H}_t)$  defines the *marginal TPP* for mark  $\kappa \in \mathcal{K}$ , that may depend on other marks via  $\mathcal{H}_t$ . Conversely, a collection of TPPs with conditional intensity  $\lambda_{\kappa}$  per  $\kappa \in \mathcal{K}$  can be *joined* to an MTPP. Using

$$\lambda(t \mid \mathcal{H}_t) = \sum_{\kappa \in \mathcal{K}} \lambda_{\kappa}(t \mid \mathcal{H}_t) \quad \text{and} \quad f(\kappa \mid t, \mathcal{H}_t) = \frac{\lambda_{\kappa}(t \mid \mathcal{H}_t)}{\lambda(t \mid \mathcal{H}_t)}$$
(4)

in equation 2 defines the conditional intensity function  $\lambda(t, \kappa \mid \mathcal{H}_t)$  of an MTPP. In fact,  $\lambda(t, \kappa \mid \mathcal{H}_t) = \lambda_{\kappa}(t \mid \mathcal{H}_t)$ . In contrast to some other neural methods (Du et al., 2016), which estimate  $\lambda(t \mid \mathcal{H}_t)$  and  $f(\kappa \mid t, \mathcal{H}_t)$ , we design our model to parametrize TPPs per mark, conditioned on the joined history of all marks.

**Hawkes Processes:** A *Hawkes MTPP* with marks K is defined by the conditional intensity

$$\lambda(t, \kappa \mid \mathcal{H}_t) = \max \left( 0, \mu_{\kappa}(t) + \sum_{(t', \kappa') \in \mathcal{H}_t} \gamma_{\kappa \kappa'}(t - t') \right)$$
 (5)

where  $\{\mu_k\}_{\kappa\in\mathcal{K}}$  is a set of *time-dependent base intensity functions* and  $\{\gamma_{\kappa\kappa'}\}_{\kappa,\kappa'\in\mathcal{K}}$  is a set of *interaction kernels*, specifying the influence of mark  $\kappa'$  on mark  $\kappa$ . If  $\gamma_{\kappa\kappa'}$  is positive, the influence of  $\kappa'$  on  $\kappa$  is called *excitatory* or *exciting*, otherwise it is called *inhibitory* or *limiting*. We use a distribution over Hawkes MTPPs to generate a large corpus of synthetic training data for our model.

**Simulation:** We use *Ogata's modified thinning algorithm* (Ogata, 1981) to generate synthetic training data from Hawkes processes and to simulate processes inferred by our model.

Inference Problem: Let  $\mathcal{C} = \{\mathcal{S}^j\}_{j=1}^m$  be a collection of m event sequences  $\mathcal{S}^j = \{(t_i^j, \kappa_i^j)\}_{i=1}^{n_j}$  observed from some system. Our objective is to *predict* or *simulate* the *next event* and estimate the *likelihood* of a (previously unseen) sequence  $\mathcal{S}$ , assuming an MTPP model. Previous neural methods *train an autoregressive encoding network on*  $\mathcal{C}$  that compresses the history  $\mathcal{H}_t$  of  $\mathcal{S}$  into some embedding  $\mathbf{h}_t$  for a neural estimate  $\hat{\lambda}(t,\kappa\mid\mathbf{h}_t)$  of the conditional intensity. In contrast, we propose a radically different foundation model approach to the inference problem. We *pretrain* a deep neural model to estimate  $\hat{\lambda}$  from a history of events *in-context of* a collection of sequences. Once trained, the model can be applied to *any*  $\mathcal{C}$  and  $\mathcal{H}_t$ , without any further training.

## 4 FOUNDATION INFERENCE MODELS FOR POINT PROCESSES

In this section, we present a *novel in-context learning method* for the MTPP intensity inference problem. In a two-step approach, we first generate a *large set of marked event sequences* from parametrized MTPPs, sampled from a *broad distribution* over MTPPs. This yields train data for a neural network recognition model, trained to estimate the *underlying known, ground-truth* intensity functions. Such *pretrained* inference model can be applied directly to real-world problems, or *swiftly finetuned* for improved performance.

## 4.1 Synthetic Dataset Generation

To design a synthetic dataset of MTTPs, we choose a distribution over Hawkes processes, defined by a distribution over conditional intensity functions of the form

$$\lambda(t, \kappa \mid \mathcal{H}_t) = \max \left( 0, \mu_{\kappa}(t) + \sum_{(t', \kappa') \in \mathcal{H}_t} z_{\kappa \kappa'} \gamma_{\kappa \kappa'}(t - t') \right) . \tag{6}$$

From a sample of this distribution, we simulate a large set of marked sequences, and record the conditional intensity for training. Let us now specify each step of the data generation in more detail.

**Intensity Function Generation:** The intensity function of a process with  $|\mathcal{K}|$  marks in equation 6 is characterized by non-negative, time-dependent functions base intensities and interaction kernels  $\mu_{\kappa}, \gamma_{\kappa\kappa'} : \mathbb{R}_+ \to \mathbb{R}_+$  and pre-factors  $z_{\kappa\kappa'} \in \{-1, 0, 1\}$  for  $\kappa\kappa' \in \mathcal{K}$ .

To generate an intensity function, we select a *single parametrized functional form* of non-negative functions for *all* base intensities and interaction kernels. Instances  $\mu_{\kappa}$  and  $\gamma_{\kappa\kappa'}$  are realized by iid. samples of the describing parameters from broad distributions for each  $\kappa, \kappa' \in \mathcal{K}$ . We capture various distributions such as periodic intensities, Poisson processes, Hawkes processes, etc. as described in Table 3.

Pre-factors  $z_{\kappa\kappa'}$  are sampled iid. from a random variable Z on  $\{-1,0,1\}$ . Due to the non-negativity of  $\gamma_{\kappa\kappa'}$ , they determine the type of influence of  $\kappa'$  on  $\kappa$ . It is *excitatory* if  $z_{\kappa\kappa'}=1$ , *inhibitory* if  $z_{\kappa\kappa'}=-1$  and *non-influencing* if  $z_{\kappa\kappa'}=0$ .

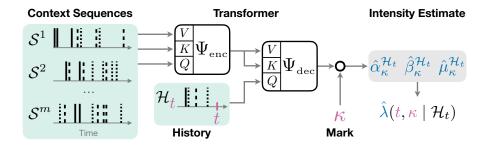

Figure 1: Schematic representation of FIM-PP. A *context* of marked event sequences  $S^{\jmath}$  is encoded by a self-attentive *transformer encoder*. The result is further processed by a *transformer decoder*, using a *history*  $\mathcal{H}_t$  of marked events before time t as queries. The final embedding is joined with an encoding of *mark*  $\kappa$ . The results is projected to a set of parameters that determine the value of the *conditional intensity function*  $\hat{\lambda}$  evaluated at  $(t, \kappa)$ .

**Simulation:** We simulate a collection  $C_{\lambda} = \{S^j\}_{j=1}^m$  of m sequences  $S_{\lambda}^j = \{(t_i^j, \kappa_i^j)\}_{i=1}^n$  of the MTPP defined by a sampled conditional intensity function  $\lambda$  from equation 6. Each sequence contains n marked events. All simulations are performed with Ogata's modified thinning algorithm.

#### 4.2 FOUNDATION INFERENCE MODEL ARCHITECTURE

We now present the architecture of FIM-PP, a pretrained deep neural network for inference of MTPPs from sets  $\mathcal{C} = \{\mathcal{S}^j\}_{j=1}^m$  of marked event sequences  $\mathcal{S}^j = \{(t_i^j,\kappa_i^j)\}_{i=1}^{n_j}$ . FIM-PP processes the *context sequences*  $\mathcal{C}$  and estimates the conditional intensity function  $\hat{\lambda}$  of an MTPP that describes the observed dynamics. Following previous intensity-based methods (Zhang et al., 2020; Zuo et al., 2021),  $\hat{\lambda}$  is implemented by a flexible parametrized function family  $\hat{\lambda}(\cdot,\kappa\mid\mathcal{H}.)$  for all  $\kappa\in\mathcal{K}$ . FIM-PP estimates its parameters by encoding the history  $\mathcal{H}_t = \{(t_i^{\text{hist}},\kappa_i^{\text{hist}})\}_{i=1}^{n_{\text{hist}}}$  before time  $t>t_{n_{\text{hist}}}^{\text{hist}}$ , subject to the processed context sequences. Figure 1 depicts a schematic representation of this approach.

To cover applications in different time scales, FIM-PP instance normalizes its inputs and renormalizes  $\hat{\lambda}$  accordingly. Appendix B provides the details. Once trained, FIM-PP can be applied for all counts of marks  $|\mathcal{K}|$  up to some fixed upper bound, similar to in-context methods in other domains (d'Ascoli et al., 2024; Berghaus et al., 2025).

We denote linear projections by  $\phi$ , feed-forward neural networks by  $\Phi$ , attention layers with residual connections by  $\psi$ , transformer encoders by  $\Psi_{\text{enc}}$  and decoders by  $\Psi_{\text{dec}}$ . Let  $E \in \mathbb{N}$  denote the model's embedding dimension.

**Context Encoding:** To encode  $\mathcal{C}$ , we combine encodings of individual sequences  $\mathcal{S}^j$ . Recognizing the importance of inter-observation times for the inference problem, we consider  $\Delta t_i^j = t_i^j - t_{i-1}^j$  as an additional feature, identifying  $t_0^j = 0$ . To encode  $\mathcal{S}^j$ , we first embed the features  $(t_i^j, \kappa_i^j, \Delta t_i^j)$  of the *i*-th event in sequence *j* into embeddings

$$\mathbf{u}_{i}^{j} = \phi_{t}(t_{i}^{j}) + \phi_{\kappa}(\kappa_{i}^{j}) + \phi_{\Delta t}(\Delta t_{i}^{j}) \in \mathbb{R}^{E}. \tag{7}$$

Sinusoidal output activations from Shukla & Marlin (2020) enhance the networks  $\phi_t$  and  $\phi_{\Delta t}$ . Let  $\mathbf{S}^j = [\mathbf{u}_1^j, \dots, \mathbf{u}_{n_j}^j] \in \mathbb{R}^{n_j \times E}$  denote the matrix of embedding of sequence  $\mathcal{S}^j$ . We extract a context sequence embedding  $\mathbf{c}_j \in \mathbb{R}^E$  by applying a transformer encoder  $\tilde{\mathbf{S}}^j = \Psi_{\mathrm{enc}}^{\mathrm{cont}}(\mathbf{S}^j) \in \mathbb{R}^{n_j \times E}$ , followed by fixed-query attention

$$\mathbf{c}_{j} = \psi^{\text{cont}}(\mathbf{q}^{\text{cont}}, \tilde{\mathbf{S}}^{j}, \tilde{\mathbf{S}}^{j}) \in \mathbb{R}^{E},$$
 (8)

where  $\mathbf{q}^{\mathrm{cont}} \in \mathbb{R}^E$  is a learnable query. The embeddings of all sequences  $\mathbf{C} = [\mathbf{c}_1, \dots, \mathbf{c}_m] \in \mathbb{R}^{m \times E}$  are finally combined by another transformer encoder  $\tilde{\mathbf{C}} = \Psi^{\mathrm{comb}}_{\mathrm{enc}}(\mathbf{C}) \in \mathbb{R}^{m \times E}$ .

**Context-aware History Encoding:** To encode the history  $\mathcal{H}_t$  of events prior to time  $t > t_{n_{\mathrm{hist}}}^{\mathrm{hist}}$ , we embed each tuple  $(t_i^{\mathrm{hist}}, \kappa_i^{\mathrm{hist}}, \Delta t_i^{\mathrm{hist}})$  into feature vectors  $\mathbf{H} = [\mathbf{u}_1^{\mathrm{hist}}, \dots, \mathbf{u}_{n_{\mathrm{hist}}}^{\mathrm{hist}}] \in \mathbb{R}^{n_{\mathrm{hist}} \times E}$ , reusing

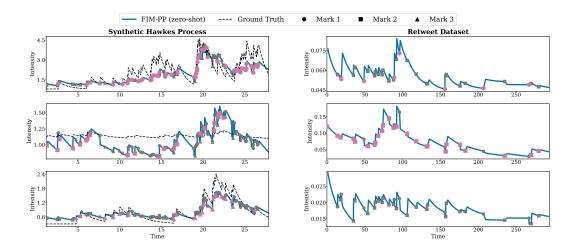

Figure 2: Example intensity estimates of FIM-PP on a synthetic Hawkes process with three marks, constant base intensity and exponential decaying kernels (left) and a real-world RETWEET dataset (right). Each row contains the intensity for one mark. Events of the same mark are colored magenta, while events for other marks are gray. For the Hawkes process, the model (blue line) estimate matches the ground-truth intensity level (black dashed line) closely. For the RETWEET data, FIM-PP estimates a mixture of many excitatory and a few inhibitory interactions.

the networks from equation 7. These history embeddings serve as the queries of a transformer decoder  $\Psi_{\rm dec}^{\rm hist}$ , which attends to the context representation  $\tilde{\mathbf{C}}$  (used as keys and values), yielding a unified encoding  $\mathbf{h}_t^{\rm hist}$  that integrates both history and context:

$$\mathbf{h}_{t}^{\text{hist}} = \Psi_{\text{dec}}^{\text{hist}}(\mathbf{H}, \tilde{\mathbf{C}}) \in \mathbb{R}^{E}$$
(9)

**Intensity Parametrization:** To extract intensity functions for all marks from  $\mathbf{h}_t^{\text{hist}}$ , we concatenate  $\mathbf{h}_t^{\text{hist}}$  and a (linear) encoding of  $\kappa'$  to  $\mathbf{v}_{\kappa'}^{\mathcal{H}_t} = [\mathbf{h}_t^{\text{hist}}, \phi_\kappa^{\text{hist}}(\kappa')] \in \mathbb{R}^{2E}$  and project them to non-negative parameter estimates

$$\hat{\alpha}_{\kappa'}^{\mathcal{H}_t} = \Phi_{\alpha}(\mathbf{v}_{\kappa'}^{\mathcal{H}_t}) \in \mathbb{R}_+, \quad \hat{\beta}_{\kappa'}^{\mathcal{H}_t} = \Phi_{\beta}(\mathbf{v}_{\kappa'}^{\mathcal{H}_t}) \in \mathbb{R}_+ \quad \text{and} \quad \hat{\mu}_{\kappa'}^{\mathcal{H}_t} = \Phi_{\mu}(\mathbf{v}_{\kappa'}^{\mathcal{H}_t}) \in \mathbb{R}_+$$
 (10)

using softplus output activations. These parametrize our neural conditional intensity estimate:<sup>2</sup>

$$\hat{\lambda}(t, \kappa' \mid \mathcal{H}_t) = \hat{\mu}_{\kappa'}^{\mathcal{H}_t} + (\hat{\alpha}_{\kappa'}^{\mathcal{H}_t} - \hat{\mu}_{\kappa'}^{\mathcal{H}_t}) \exp\left(-\hat{\beta}_{\kappa'}^{\mathcal{H}_t}(t - t_{n_{\text{hist}}})\right)$$
(11)

This parametrization is flexible, yet interpretable. Immediately after incorporating a new event in the history, the intensity jumps to  $\hat{\alpha}_{\kappa'}^{\mathcal{H}_t}$ . In a long interval without events, the intensity converges towards  $\hat{\mu}_{\kappa'}^{\mathcal{H}_t}$ . The convergence speed is determined by  $\hat{\beta}_{\kappa'}^{\mathcal{H}_t}$ .

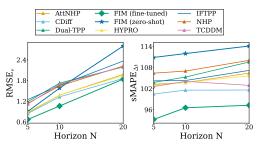

**Training:** To train FIM-PP on a set of sequences  $\mathcal{C}_{\lambda}$  from our synthetic train data, we select a *target sequence*  $\mathcal{T} \in \mathcal{C}_{\lambda}$  to provide a history of events and use remaining sequences  $\mathcal{C}_{\lambda} \setminus \{\mathcal{T}\}$  as context. We subsample  $\mathcal{C}_{\lambda}$ , truncate sequences and vary the number of marks throughout training, which enables us to apply a pretrained FIM-PP in a wide range of (real-world) settings. Our train objective is the next-event negative log likelihood of the target sequence:

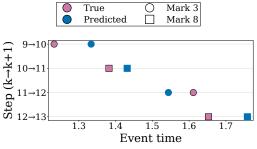

$$\mathcal{L}_{\text{NLL}} = \sum_{\kappa \in \mathcal{K}} \int_0^T \hat{\lambda}(s, \kappa \mid \mathcal{H}_s) ds - \sum_{(t, \kappa) \in \mathcal{T}} \hat{\lambda}(t, \kappa \mid \mathcal{H}_t)$$
 (12)

Appendix C discussed the training of FIM-PP in greater detail.

**Finetuning:** FIM-PP can be finetuned on the train split  $\mathcal C$  of an evaluation dataset, minimizing  $\mathcal L_{NLL}$ . For each iteration, a random sequence  $\mathcal T \in \mathcal C$  in the train split is selected as the target sequence. The remaining sequences  $\mathcal C \setminus \{\mathcal T\}$  serve as context. Finetuning progress is monitored by processing target sequences from the validation split, given the train split context.

<sup>&</sup>lt;sup>2</sup>Note that the functional form of  $\hat{\lambda}$  is similar to the conditional intensity in Zhang et al. (2020).

- (a) Mean performance metrics across five different datasets for different horizon lengths.
- (b) Next event prediction on Taxi after fine-tuning

Figure 3: (a) shows that FIM-PP (zs) is competitive but slightly worse than the baseline models. FIM-PP (f) however performs best among all horizon lengths. (b) shows that FIM-PP (f) also reliably captures patterns in the Taxi dataset.

# 5 EXPERIMENTS

In this section, we repeat the experiments by Zeng et al. (2024), who introduced CDiff, a recent state-of-the-art diffusion-based marked event sequence forecasting model. They compare their method against a range of intensity-based and intensity-free baselines, on common benchmark datasets, evaluated on standard metrics. In the following, we recall their experimental setup, describe the pretraining and application of FIM-PP, before presenting and analyzing our results.

## 5.1 EXPERIMENTAL SETUP

**Prediction Task:** Given a sequence of events  $S = \{(t_i, \kappa_i)\}_{i=1}^n$ , the task is to predict the *next*  $N \in \mathbb{N}$  events following S, where N is the *prediction horizon length*. We denote the ground-truth continuation by  $S_{\text{final}}^N$  and the model prediction by  $\hat{S}_{\text{final}}^N$ . We refer to the case N = 1 as *next-event prediction* and to N > 1 as *multi-event prediction*.

**Evaluation Metrics:** We evaluate predictions by comparing  $\hat{\mathcal{S}}_{\text{final}}^N$  with  $\mathcal{S}_{\text{final}}^N$  across five metrics. For N>1, we report the Optimal Transport Distance (OTD) (Mei et al., 2019); event count error (RMSE<sub>e</sub>), comparing the number of predicted and true events per mark; and two standard regression metrics on waiting times: RMSE<sub> $\Delta t$ </sub> and sMAPE<sub> $\Delta t$ </sub>. For the special case N=1, OTD and RMSE<sub>e</sub> are not applicable, and we instead report next-event mark prediction accuracy (Acc). Formal definitions of all metrics are provided in Appendix E.

**Evaluation Data:** We benchmark on five widely used real-world datasets: TAXI, TAOBAO, STACK-OVERFLOW, AMAZON, and RETWEET. These datasets vary in the number of marks, sequence lengths, and event counts, making them a strong testbed for evaluating the broad applicability of FIM-PP. We use the preprocessing and train/test/validation splits of Zeng et al. (2024). Appendix D contains further details, including dataset statistics and original sources.

**Baselines:** We compare FIM-PP against methods falling into two categories: models that learn joint distributions over multiple events, and autoregressive approaches such as FIM-PP. The first category includes Dual-TPP (Deshpande et al., 2021), HYPRO (Xue et al., 2022), and the Cross-diffusion Model (CDiff) (Zeng et al., 2024). The second category further splits into intensity-based and intensity-free approaches. Intensity-based baselines are the Neural Hawkes Process (NHP) (Mei & Eisner, 2017), and the Attentive Neural Hawkes Process (A-NHP) (Mei et al., 2022). Intensity-free baselines are the Intensity-Free Temporal Point Process (IFTPP) (Shchur et al., 2020), and the Temporal Conditional Diffusion Denoising Model (TCDDM) (Lin et al., 2022).

#### 5.2 Pretraining and Applying FIM-PP

We pretrain a single FIM-PP on a synthetic dataset containing 14.4M events, simulated from 72K Hawkes processes of diverse kernels, and sparsity levels, and varying number of marks, sequences, and events. Appendix A contains the details. The model has 16M parameters and supports up to

Table 1: Performance on four real-world datasets, predicting N=20 events. Results for baseline methods were extracted from Zeng et al. (2024). We report mean and standard deviation over 10 trials for two metrics. Best results are bold.

 $|\mathcal{K}|=22$  marks, which covers all evaluation datasets. Further pretraining details are provided in Appendix C.

In zero-shot mode, we apply the pretrained model directly to all evaluation datasets, and label the results by FIM-PP (zs). We also experiment with finetuning FIM-PP on the train split of all evaluation datasets, and label these results by FIM-PP (f). FIM-PP utilizes up to 2000 sequences from the train split of an evaluation dataset as context, limited only by the maximum number of sequences seen during training. Sequences in the test split define the history. Finally, for multi-event prediction, FIM-PP simulates events autoregressively, similar to other (intensity-based) baselines.

Figure 2 shows intensities inferred by FIM-PP in zero-shot mode, both from a synthetic Hawkes process (in-distribution generalization), and from the RETWEET dataset (out-of-distribution generalization). In what follows, we quantitatively evaluate FIM-PP.

## 5.3 Multi-Event Prediction

Table 1 reports OTD and sMAPE $_{\Delta t}$  results for N=20 and four datasets. Remarkably, FIM-PP achieves competitive performance in zero-shot mode, matching or surpassing specialized baselines on TAXI and RETWEET data. This shows that, solely from pretraining on synthetic data, the model can translate contextual patters into accurate multi-event predictions, without any further training or supervision.

The same table also demonstrates the effectiveness of finetuning. The finetuned FIM-PP (f) consistently outperforms both FIM-PP (zs) and all baselines, across the four datasets and nearly all metrics. Additional experiments with shorter horizons (N=10,5) and alternative metrics (RMSE<sub>e</sub>, RMSE<sub> $\Delta t$ </sub>) are reported in Appendix F, providing a complementary view.

Figure 3a summarizes performance across horizon lengths by averaging results over all datasets. In aggregate, FIM-PP (zs) performs on par with the baselines, while FIM-PP (f) consistently outperforms them, agreeing with our previous analysis. We attribute the effectiveness of finetuning to two factors: (i) the strong prior encoded into the model's weights through pretraining on our synthetic distribution, which provides a good initialization for finetuning; and (ii) the flexibility of the foundation model architecture, which enables *direct access* to patterns in the train split *during evaluation*.

#### 5.4 Next-Event Prediction

The *next-event prediction* task is a special case of multi-event prediction, but it differs in nature. Whereas multi-event prediction requires estimating the *distribution* over a set of future events, next-

Table 2: Next-event prediction performance on two real-world datasets, displayed with mean and standard deviation over 10 trials. Results for baseline methods were extracted from Zeng et al. (2024). Best results are bold.

		TAX	I	Таовао			
Method	$\overline{RMSE_{\Delta t}}$	Acc	$\mathrm{sMAPE}_{\Delta t}$	$\overline{RMSE_{\Delta t}}$	Acc	$\mathrm{sMAPE}_{\Delta t}$	
A-NHP	$0.32 \pm 0.00$	0.91 ±0.01	$85.13 \pm 0.26$	$0.53 \pm 0.00$	$0.47_{\ \pm 0.01}$	$129.13 \pm 1.35$	
Dual-TPP	$0.34 \pm 0.01$	$0.91 \pm 0.01$	$89.12 \pm 0.75$	$0.53 \pm 0.01$	$0.47{\scriptstyle~ \pm 0.02}$	$131.43 \pm 1.99$	
NHP	$0.34 \pm \scriptstyle{0.01}$	$0.91 \pm 0.01$	$90.63 \pm 0.61$	$0.53 \pm 0.00$	$0.46 \pm 0.01$	$133.69 \pm 2.25$	
IFTPP	$0.38 \pm 0.01$	$0.90 \pm 0.01$	$90.03 \pm 0.47$	$0.53 \pm 0.01$	$0.45 \pm 0.01$	$126.01 \pm 1.48$	
CDiff	$0.34{\scriptstyle~ \pm 0.01}$	$\boldsymbol{0.91} \pm 0.00$	$87.12 \pm \scriptstyle{0.61}$	$0.52 \pm 0.01$	$0.48 \pm 0.00$	$127.12 \pm 1.36$	
FIM-PP(zs)	$0.15 \pm 0.00$	$0.41 \pm 0.03$	$69.37 \pm 0.91$	1.41 ±0.03	$0.09 \pm 0.01$	$163.34 \pm 0.51$	
FIM-PP(f)	$0.15 \pm 0.00$	$0.69 \pm 0.01$	$63.02 \pm 0.48$	$9.31 \pm 0.15$	$0.39 \pm 0.01$	$138.46 \pm 2.69$	

event prediction focuses on accurately forecasting a *single* event. This distinction is also reflected in the evaluation metrics (see Appendix E)<sup>3</sup>.

Table 2 reports next-event prediction results (N=1) on two real-world datasets. FIM-PP (zs) performs well on event-time prediction for TAXI, but struggles with mark accuracy on TAXI and with both event-time and mark accuracy on TAOBAO. These difficulties can be explained by dataset-specific patterns: sequences in TAXI often alternate consistently between two marks, a pattern unlikely to appear in the Hawkes-process prior. In contrast, TAOBAO is heavily dominated by a single mark and occasionally exhibits long waiting times. Again, patterns not covered by our pretraining distribution.

Compared to the baselines, which easily incorporate such patterns during training, FIM-PP (zs) cannot reproduce them accurately from the context alone. Appendix G further analyzes these out-of-distribution patterns.

When finetuned, however, FIM-PP can adapt to (some) of these characteristics. Table 2 shows substantial improvements in mark prediction accuracy (Acc) after finetuning, and Figure 3 illustrates that FIM-PP (f) successfully recovers the alternating pattern in the TAXI dataset. Nevertheless, FIM-PP (f) still lags behind the baselines in mark prediction accuracy (Acc). In Appendix G, we suggest broadening the synthetic pretraining distribution to better capture such distinctive patterns upfront.

#### 6 Conclusions

In this work, we introduced FIM-PP, the first *Foundation Inference Model* capable of inferring marked temporal point processes (MTPPs) from real-world data. Our experiments empirically demonstrated that a *single* FIM-PP, pretrained on synthetic, Hawkes-process data only, is able to match the predictive performance of other intensity-based MTPP methods in *zero-shot mode*, i.e. *without any further training*. The pretraining distribution also provides an excellent initialization for *finetuning* FIM-PP, which rapidly improves its performance in just a few iterations.

**Limitations:** Hawkes processes do not describe all real-world patterns accurately, biasing our model in zero-shot mode. Moreover, a pretrained FIM-PP is restricted by a fixed upper bound on the number of marks  $|\mathcal{K}|$  it can predict. The number of sequences and events to be passed as context during evaluation is limited by the maximum number of events passed during training. In applications surpassing this limit, FIM-PP may not have access to all available context patterns.

**Future Work:** Future work will *broaden the pretraining distribution* beyond Hawkes processes, to capture more real-world patterns in zero-shot mode and provide an even better initialization for finetuning. *Intensity-free* methods have demonstrated astonishingly good predictive performance (Panos, 2024). We will explore incorporating such intensity-free methods into our amortized incontext learning approach.

 $<sup>^3</sup>$ For instance, mark accuracy (Acc) targets the correctness of one event, while RMSE $_e$  compares histograms over multiple events.

# 7 REPRODUCIBILITY STATEMENT

Our core methodology consists of two parts: *synthetically generated training data* and a *foundation model* deep neural network for inference of marked temporal point processes. *Data generation* is described extensively in Section 4.1 and complemented by Appendix A, which covers the exact hyperparameters and choices required to reproduce our train dataset. Section 4.2 discussed the architecture of FIM-PP. *Training details*, including hyperparameter choices and sizes of submodules, are described in Appendix C

We include the code for data generation, the model implementation and the model weights in the supplementary material.<sup>4</sup>

The *real-world datasets* for our experiment are described in Appendix D, including the data sizes and number of marks. For data sourcing and pre-processing, we follow Zeng et al. (2024), as discussed in Appendix D.

Finally, the *evaluation metrics* for all experiments are described in Appendix E.

# A DATA GENERATION

To train our Foundation Inference Model, we generate a comprehensive synthetic dataset of marked temporal point processes. Each process is an instance of a multivariate Hawkes process. The conditional intensity function  $\lambda(t, \kappa \mid \mathcal{H}_t)$  at time  $t \in \mathbb{R}_+$  for a mark  $\kappa \in \mathcal{K}$  given a history of marked events  $\mathcal{H}_t = \{(t_i, \kappa_i) \mid t_i < t\}$  is defined as

$$\lambda(t, \kappa \mid \mathcal{H}_t) = \max \left( 0, \mu_{\kappa}(t) + \sum_{(t', \kappa') \in \mathcal{H}_t} z_{\kappa \kappa'} \gamma_{\kappa \kappa'}(t - t') \right) , \tag{13}$$

where  $\mu_{\kappa}$  is the time-dependent base intensity for mark  $\kappa$ ,  $\gamma_{\kappa\kappa'}$  is the interaction kernel between  $\kappa$  and  $\kappa' \in \mathcal{K}$  and  $z_{\kappa\kappa'} \in \mathbb{R}$  are sampled pre-factors of the interaction, varying the interaction behavior further.

To the best of our knowledge, no open-source solution for sampling such Hawkes processes with time-dependent base intensity functions exists. Hence, we implemented an efficient custom sampling library for such processes in C++. We will release the source code of this library in the supplementary material of our work.

## A.1 DATASET CONFIGURATIONS

We sample Hawkes processe instances over a set of marks K in equation 13 in two stages.

At first, the functional forms for the base intensities  $\mu_{\kappa}$  and interaction kernels  $\gamma_{\kappa\kappa'}$  are drawn from a library of parametric functions. The parameters for these functions are then sampled from specified prior distributions. Our used functional forms and their parameters are summarized in Table 3. The parameter ranges were chosen more or less arbitrarily so that the paths look *realistic*. We keep these choices fixed and did not modify them based on the performance on our evaluation sets in order to prevent overfitting to those, which would be contrary to the concept of a foundation model.

The pre-factors further diversify the sampled processes by introducing sparse connectivity and inhibitory effects. For each process with interactions, we choose one of two pre-factor distributions  $Z_{\text{strong}}$  and  $Z_{\text{sparse}}$  on  $\{-1,0,1\}$ , which differ by their induced connectivity:

$$Z_{\text{strong}} = \text{Categorical}(-1:0.06, 0:0.4, 1:0.54)$$
 (14)

$$Z_{\text{sparse}} = \text{Categorical}(-1:0.01, 0:0.9, 1:0.09)$$
 (15)

In other words, for  $Z_{\rm strong}$ , only 40% of interactions will be non-influencing, while for  $Z_{\rm sparse}$ , 90% of interactions will be non-influencing. For influencing interactions, 90% will be excitatory, while 10% will be inhibitory.

Once the full intensity function for a process is defined, event sequences are generated using Ogata's modified thinning algorithm.

#### A.2 DATASET SIZE

We sample instances of every Hawkes process configuration in Table 3, and simulate them for different number of marks, sequences and events, detailed in Table 4. In total, our training data consisted of 72k processes and 14.4M events.

### **B** Instance Normalization

To ensure that FIM-PP can generalize across datasets with vastly different time scales, we introduce an instance normalization scheme that makes the model agnostic to the absolute units of time. Let  $\mathcal{C} = \{\mathcal{S}^j\}_{j=1}^m$  denote a context of FIM-PP, i.e. a set of marked event sequences  $\mathcal{S}^j = \{(t_i^j, \kappa_i^j)\}_{i=1}^{n_j}$ . Identifying  $t_0^j = 0$ , we define the inter-event times as  $\Delta t_i^j = t_i^j - t_{i-1}^j$  and the maximum inter-event time in the context as

$$\Delta t_{\text{max}}^{\text{cont}} = \max_{j=1,\dots,m} \max_{i=1,\dots,n_j} \Delta t_i^j \quad . \tag{16}$$

All time-related inputs to the model, including context event times  $t_i^j$ , inter-event times features  $\Delta t_i^j$ , and history event times (e.g. from a target sequence during training) t, are scaled by the maximum inter-event time:

$$t' = \frac{t}{\Delta t_{\text{max}}^{\text{cont}}}.$$
 (17)

This transformation maps all temporal information to a canonical scale where the largest inter-event gap becomes 1.

This change of time variable also transforms the intensity function. To preserve the number of expected events within a differential interval, the intensities must be related by  $\lambda(t)dt = \lambda'(t')dt'$ .

Table 3: Summary of the parametrized base intensities and interaction kernels of Hawkes processes used in our synthetic data generation. The parameters of each configuration are sampled from uniform distributions, covering a wide range of processes.

Dataset Configuration	Base Intensity $\mu(t)$	Interaction Kernel $\gamma(t)$	Parameter Distributions
Constant Base & Exponential Kernel (no interactions)	Constant $\mu(t) = c_0$	Exponential Decay $\gamma(t) = \alpha e^{-\beta t}$ $(\gamma_{ij, i \neq j} = 0)$	$c_0 \sim \mathcal{U}(0.01, 1.3)$ $\alpha \sim \mathcal{U}(0.005, 1.0)$ $\beta \sim \mathcal{U}(0.001, 10.0)$
Constant Base & Exponential Kernel	Constant $\mu(t) = c_0$	Exponential Decay $\gamma(t) = \alpha e^{-\beta t}$	$c_0 \sim \mathcal{U}(0.01, 1.3)$ $\alpha \sim \mathcal{U}(0.005, 1.0)$ $\beta \sim \mathcal{U}(0.001, 10.0)$
Sinusoidal Base & Exponential Kernel	Sinusoidal $\mu(t) = A\sin(\omega(t-\gamma)) + c_0$	Exponential Decay $\gamma(t) = \alpha e^{-\beta t}$	$\begin{array}{l} c_0 \sim \mathcal{U}(0.05, 0.15) \\ A \sim \mathcal{U}(0.0, 10.0) \\ \omega \sim \mathcal{U}(0.1, 15.0) \\ \gamma \sim \mathcal{U}(0.0, 5.0) \\ \alpha \sim \mathcal{U}(0.1, 0.6) \\ \beta \sim \mathcal{U}(0.8, 2.0) \end{array}$
Gamma Base & Exponential Kernel	Gamma Shape + Constant $\mu(t) = At^p e^{-\beta_0 t} + c_0$	Exponential Decay $\gamma(t) = \alpha e^{-\beta_1 t}$	$\begin{aligned} c_0 &\sim \mathcal{U}(0.1, 1.3) \\ A &\sim \mathcal{U}(10.0, 50.0) \\ p &\sim \mathcal{U}(1.0, 2.0) \\ \beta_0 &\sim \mathcal{U}(1.0, 10.1) \\ \alpha &\sim \mathcal{U}(0.005, 1.0) \\ \beta_1 &\sim \mathcal{U}(0.001, 10.0) \end{aligned}$
Poisson Process	Constant $\mu(t) = c_0$	Zero Kernel $\gamma(t)=0$	$c_0 \sim \mathcal{U}(0.01, 1.3)$
Constant Base & Rayleigh Kernel	Constant $\mu(t) = c_0$	Rayleigh $\gamma(t) = a_0 \frac{(t - t_{\rm shift})}{a_1^2} \exp \left(-\frac{(t - t_{\rm shift})^2}{2a_1^2}\right)$	$c_0 \sim \mathcal{U}(0.01, 1.3)$ $a_0 \sim \mathcal{U}(0.001, 1.0)$ $a_1 \sim \mathcal{U}(0.05, 0.25)$ $t_{\mathrm{shift}} \sim \mathcal{U}(0.0, 0.1)$

Table 4: For each dataset configuration, we sample Hawkes processes with varying numbers (#) of marks, sequences and events per sequence.

# Marks	# Samples	# Sequences	# Events per Sequence
1	1000	2000	100
5	1000	2000	100
10	1000	2000	100
15	1000	2000	100
22	5000	2000	100

Since  $dt = \Delta t_{\text{max}}^{\text{cont}} dt'$ , it follows that the intensity in the normalized time domain,  $\lambda'(t')$ , is a scaled version of the original:

$$\lambda'(t') = \Delta t_{\text{max}}^{\text{cont}} \cdot \lambda(t). \tag{18}$$

Consequently, the model is trained to predict this normalized intensity  $\lambda'(t')$ . During inference, to obtain the intensity in the original, real-world time scale, the model's output is simply denormalized by dividing by the same constant  $\Delta t_{\rm max}^{\rm cont}$ . This entire process allows the FIM to learn scale-invariant temporal dynamics, a key requirement for effective zero-shot inference on unseen data.

# C TRAINING DETAILS

Our Foundation Inference Model was trained on the comprehensive synthetic datasets described in Appendix A. The training took about 5 days on a single NVIDIA A100-80GB.

#### C.1 Data Handling and Batching

Each sample in our dataset represents a single underlying process, comprising up to 2000 distinct time series paths. During training, we dynamically partition these paths into context and inference sets for each batch.

On-the-fly Path Selection For each sample, we randomly select a single path  $(P_{\text{inference}} = 1)$  to serve as the inference target. The remaining paths are designated as the context set. To train a model that is robust to varying amounts of contextual information, the number of context paths presented in each training step is randomized. Specifically, for each sample in a batch, we uniformly sample a number of context paths between a minimum of 400 and a maximum of 2000.

**Variable Sequence Lengths** As a form of data augmentation, we also vary the length of the historical sequences. For 90% of the training batches, all sequences (both context and inference) are truncated to a random length chosen uniformly from the interval [15, 100]. For the remaining 10% of batches, the full sequence length of 100 events is used. This strategy encourages the model to make reliable predictions from both short and long historical contexts. For validation, we use fixed, full-length sequences to ensure consistent and comparable evaluation metrics.

#### C.2 HYPERPARAMETERS AND OPTIMIZATION

The model architecture is based on the Transformer Vaswani et al. (2017). Context sequences are processed by a 4-layer Transformer encoder, and the resulting path summaries are further refined by a 2-layer Transformer encoder. The history of the target sequence is processed by a 4-layer Transformer decoder, which attends to the context summary as memory. Both encoders and the decoder use 4 attention heads and a hidden dimension of 256. The final intensity parameters  $(\mu, \alpha, \beta)$  are predicted by three separate Multi-Layer Perceptrons (MLPs), each with two hidden layers of 256 units.

In total, our model has 16.1 million trainable parameters.

We trained the model using the AdamW optimizer Loshchilov & Hutter (2019) with a learning rate of  $5 \times 10^{-5}$  and a weight decay of  $10^{-4}$ . To accelerate computation, we utilized bfloat16 mixed-precision training.

## C.3 TRAIN OBJECTIVE

We use the standard negative log-likelihood (NLL) for a marked temporal point process as the train objective for FIM-PP. By Section 3, the MTPP density at a sequence of events  $\mathcal{S} = \{(t_i, \kappa_i)\}_{i=1}^n$  in the interval [0, T] is

$$f\left(\left\{\left(t_{i}, \kappa_{i}\right\}_{i=1}^{n}\right) = \left[\prod_{i=1}^{n} \lambda(t_{i}, \kappa_{i} \mid \mathcal{H}_{t_{i}})\right] \exp\left(-\int_{0}^{T} \lambda(s \mid \mathcal{H}_{s}) ds\right). \tag{19}$$

Thus, the NLL of a target sequence under the distribution induced the model's predicted intensity function  $\hat{\lambda}$  is

$$\mathcal{L}_{\text{NLL}} = \sum_{\kappa \in \mathcal{K}} \hat{\Lambda}(T, \kappa) - \sum_{(t, \kappa) \in \mathcal{T}} \hat{\lambda}(t, \kappa \mid \mathcal{H}_t) . \tag{20}$$

where  $\hat{\Lambda}(T,\kappa)=\int_0^T\hat{\lambda}(s,\kappa\mid\mathcal{H}_s)ds$  is the predicted integrated intensity. We approximate the integral using Monte Carlo integration

$$\hat{\Lambda}(T,\kappa) \approx \frac{T}{N_{\text{MC}}} \sum_{i=1}^{N_{\text{MC}}} \hat{\lambda}(s_i, \kappa \mid \mathcal{H}_{s_i}), \tag{21}$$

with  $N_{MC} = 100$  samples and  $s_i \sim \mathcal{U}(0, T)$ .

## D EVALUATION DATASETS

To evaluate the inference capabilities of FIM-PP, we use five widely-recognized real-world datasets that were not seen during training:

**AMAZON** This dataset comprises sequences of product reviews from users on the Amazon platform, collected over a ten-year period from 2008 to 2018 Ni et al. (2019). Each sequence represents the review history of a single user. An event is defined by the timestamp of a review, and its mark corresponds to one of 16 distinct product categories. The analysis is performed on a subset of 5,200 of the most active users to ensure sequences are sufficiently long for meaningful analysis.

**TAXI** Derived from New York City's public taxi trip records, this dataset captures the operational patterns of taxi drivers. Each sequence corresponds to the activity log of an individual driver. Events are either pick-ups or drop-offs, and the event marks are defined by the combination of the event type (pick-up/drop-off) and the borough where it occurred, resulting in 10 unique marks. The dataset consists of sequences from a random sample of 2,000 drivers.

**TAOBAO** This dataset originates from the 2018 Tianchi Big Data Competition and contains logs of user interactions on the Taobao e-commerce platform over a period in late 2017 Zhu et al. (2018). The sequences track the behavior of anonymous users, including actions like browsing and purchasing. The 17 event types correspond to different product category groups. For the evaluation, sequences from the 2,000 most active users are utilized.

**STACKOVERFLOW** Sourced from the popular question-and-answering website StackOverflow, this dataset tracks the awarding of achievement badges to users over a two-year span Leskovec & Krevl (2014). Each sequence represents a user's history of earned badges. The events are the timestamps when badges were awarded, and the marks are the 22 different types of badges available on the platform. The evaluation subset includes 2,200 active users.

**RETWEET** This dataset tracks the dynamics of information spread through time-stamped user retweet sequences Zhou et al. (2013). Each sequence corresponds to the retweet history of an individual user. An event is defined by the timestamp of a retweet, and its mark is categorized into one of three types based on the influence of the original poster: "small" (fewer than 120 followers), "medium" (fewer than 1,363 followers), and "large" (all other users). The analysis is performed on a subset of 5,200 active users.

For all real-world datasets, we use the pre-processing and splits from Zeng et al. (2024).

To compare against the other models, FIM-PP uses the sequences which the other models used for training as context and used the same inference sequences for evaluation.

#### E EVALUATION METRICS

Following Zeng et al. (2024), we adopt a comprehensive set of metrics to evaluate both the temporal and categorical aspects of the predicted sequences. Let  $\mathcal{S}_{\text{future}} = \{(t_i, \kappa_i)\}_{i=1}^N$  be a ground truth sequence of N future events, and let  $\hat{\mathcal{S}}_{\text{future}}$  be the corresponding predicted sequence. The metrics are defined based on the sequence of inter-arrival times  $\Delta \mathbf{t} = [\Delta t_1, \dots, \Delta t_N]$  (where  $\Delta t_i = t_i - t_{i-1}$ ) and the sequence of marks.

**Optimal Transport Distance (OTD)** We use the Optimal Transport Distance (OTD) to provide a holistic measure of similarity between the predicted and ground truth event sequences (Mei et al., 2019). OTD calculates the minimum cost required to transform the predicted sequence  $\hat{S}_{\text{future}}$  into the ground truth sequence  $S_{\text{future}}$  through a series of operations (insertions, deletions, and substitutions), each associated with a cost. This metric effectively captures discrepancies in timing, marks, and the total number of events.

**RMSE** on Event Counts (RMSE<sub>e</sub>) This metric evaluates how well the model captures the distribution of event types in the predicted sequence. For each event type  $\kappa \in \mathcal{K}$ , we count its occurrences in the ground truth sequence  $(C_{\kappa})$  and the predicted sequence  $(\hat{C}_{\kappa})$ . The RMSE<sub>e</sub> is the root mean squared error over the vector of these counts, averaged across all m test sequences:

$$RMSE_e = \sqrt{\frac{1}{m} \sum_{j=1}^{m} \sum_{\kappa \in \mathcal{K}} (C_{j,\kappa} - \hat{C}_{j,\kappa})^2}$$
 (22)

**Event Type Accuracy (Acc)** This metric directly measures the model's ability to predict the correct event type at each position in the sequence. It is calculated as the fraction of events for which the predicted mark  $\hat{\kappa}_i$  matches the ground truth mark  $\kappa_i$ , averaged over all test sequences. This provides a strict, position-wise evaluation of the categorical predictions.

$$Acc = \frac{1}{m} \sum_{j=1}^{m} \frac{1}{N} \sum_{i=1}^{N} \mathbb{I}(\kappa_{j,i} = \hat{\kappa}_{j,i})$$
 (23)

where  $\mathbb{I}(\cdot)$  is the indicator function. Unlike RMSE<sub>e</sub>, which assesses the overall distribution of event types, accuracy penalizes mispredictions at specific positions, making it a more challenging metric for sequential order. A higher accuracy indicates better performance.

**Time-series Forecasting Metrics** To specifically assess the accuracy of the predicted inter-arrival times  $\Delta t$ , we report two standard time-series forecasting metrics.

• RMSE on Inter-arrival Times (RMSE $_{\Delta t}$ ): The standard root mean squared error between the predicted and true vectors of inter-arrival times.

$$RMSE_{\Delta t} = \sqrt{\frac{1}{m} \sum_{j=1}^{m} \frac{1}{N} \sum_{i=1}^{N} (\Delta t_{j,i} - \hat{\Delta} t_{j,i})^2}$$
 (24)

• Symmetric Mean Absolute Percentage Error (sMAPE $_{\Delta t}$ ): A normalized version of MAPE that is less sensitive to outliers and zero values.

$$sMAPE_{\Delta t} = \frac{100}{m} \sum_{i=1}^{m} \frac{1}{N} \sum_{i=1}^{N} \frac{2|\Delta t_{j,i} - \hat{\Delta} t_{j,i}|}{|\Delta t_{j,i}| + |\hat{\Delta} t_{j,i}|}$$
(25)

### F ADDITIONAL RESULTS

The experimental setup defined by Zeng et al. (2024) covers four metrics (OTD, RMSE<sub>e</sub>, RMSE<sub> $\Delta t$ </sub>, sMAPE<sub> $\Delta t$ </sub>) and five real-world datasets (TAXI, TAOBAO, STACKOVERFLOW, AMAZON and RETWEET). Table 5, Table 6 and Table 7 contain the long horizon results for all these datasets and metrics for horizon sizes N=20, N=10 and N=5, respectively.

## G CHALLENGES IN NEXT EVENT PREDICTION

Our evaluations in table 2 reveal that FIM-PP in zero-shot mode already performs well for next event time prediction. It however gets a noticeably worse error in the next event type prediction. Up on investigating this, we found that many of the real-world datasets have specific patterns (such as oscillations between two marks) that FIM-PP (zs) struggles to capture (see fig 4). After fine-tuning, it is however able to spot these patterns well (see fig 5). This might also explain why FIM-PP performs better on long-horizon tasks: The specific order of the events does not matter here.

Moreover, we found that our model performed poorly on the Taobao dataset compared to other datasets, and even the fine-tuned version predicts some event-time outliers which drag down the  $RMSE_{\Delta t}$ . While we do not have a good analysis of this shortcoming yet, we suspect it to be caused by the fact that the Taobao dataset is significantly dominated by a single mark and sometimes has long waiting times.

We hypothesize that the underlying reason for these two shortcomings is that our synthetic dataset distributions does not capture these patterns well. We are planning to investigate this further and to update our synthetic distribution to include such patterns and provide an updated version of FIM-PP.

Table 5: Prediction of N=20 events in test sequences of five real-world datasets. Error-bars indicate the standard deviation over 10 trials. Results for the baseline methods were extracted from Zeng et al. (2024). Best results are bold.

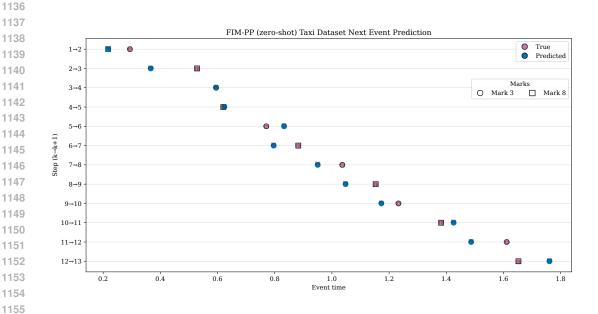

Figure 4: FIM-PP in zero-shot mode struggles to predict the next event type right if the dataset has alternating patterns such as here for the Taxi dataset.

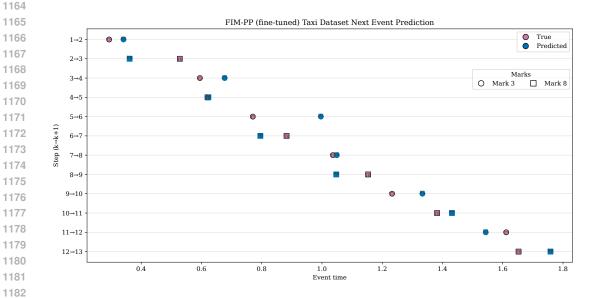

Figure 5: After fine-tuning, FIM-PP is able to spot the alternating pattern between mark 3 and mark 8 in the Taxi dataset.
