

# GradNormIR: When Should We Update the Dense Retriever in Evolving Corpora?

Anonymous ACL submission

## Abstract

A dense retriever learns text embeddings to fetch relevant documents from a database in response to queries. However, real-world document streams constantly evolve, often diverging from the retriever’s original training distribution. Indexing these documents without preemptive measures (e.g., updating or retraining) can lead to retrieval failures for future test queries. Hence, it is crucial to detect when to update dense retrievers before those test queries arrive, ensuring the retrieval system’s maintenance. To address this challenge, we introduce a novel task of predicting whether a given corpus is out-of-domain (OOD) for a dense retriever before indexing. This task enables us to assess whether using the current retriever on the given corpus creates vulnerabilities for future test queries. We propose **GradNormIR**, a novel unsupervised method that leverages gradient norms to detect OOD documents within a given corpus. Experiments on the BEIR benchmark demonstrate that our method facilitates timely retriever updates in evolving corpora, providing valuable guidance for building an efficient and robust retrieval system.

## 1 Introduction

With the exponential growth of digital content, information retrieval (IR) systems have become crucial for providing users with relevant information from vast repositories (Bajaj et al., 2016; Kwiatkowski et al., 2019). Unlike traditional sparse retrieval methods (Robertson et al., 2009; Ramos et al., 2003) that rely on lexical overlap, dense retrievers (Karpukhin et al., 2020; Izacard et al., 2022) leverage semantic representations to capture query intent and match conceptually similar documents, transcending the limitations of exact word matching. Hence, dense retrievers have acquired much attention in scenarios requiring high-precision semantic matching, such as question-answering and personalized search. During train-

Figure 1: **Motivation.** In evolving corpora, indexing a document corpus that dense retrievers cannot generalize leads to performance degradation. Thus, detecting an OOD corpus without available queries before indexing becomes crucial for maintaining retrieval effectiveness. We propose GradNormIR, an unsupervised method that leverages gradient norms to predict such OOD corpus.

ing, dense retrievers are optimized to maximize the embedding similarity between queries and relevant passages while minimizing the similarity for irrelevant ones (Karpukhin et al., 2020; Izacard et al., 2022). During indexing, document embeddings are precomputed and stored in a retrieval index. At inference, given a test query, the retriever fetches relevant documents based on similarity scores.

In the real world, document corpora evolve rapidly due to technological advancements, societal changes, and emerging trends. This evolution presents a significant challenge for dense retrievers, which often struggle to generalize to unseen documents in zero-shot settings (Chen et al., 2023). This challenge becomes even more critical in retrieval

augmented generation (RAG) systems (Lewis et al., 2020), where the retriever’s failure directly affects downstream tasks (Petroni et al.; Li et al., 2023a). As shown in an example of Fig. 1, consider a scenario where a corpus about Google’s new quantum computing chip, *Willow*, is introduced. For a query like "Tell me how the Willow works.", the dense retriever may mistakenly retrieve the documents about the song *Willow* by Taylor Swift. This occurs because the retriever previously trained on the song *Willow*, may not have adapted to the new context of quantum computing. Therefore, it is critical to anticipate when a retriever is likely to fail on a new corpus. This allows us to proactively determine when to update the retriever before queries are made, ensuring robustness in dynamically evolving document streams.

This challenge is closely related to the out-of-domain (OOD) generalization problem. Several approaches in IR aim to enhance a retriever’s test performance on unseen queries or documents that significantly differ from the training data (Izacard et al., 2022; Wang et al., 2021; Chen et al., 2022; Yu et al., 2022; Wang et al., 2021; Kasela et al., 2024; Besta et al., 2024; Chen et al., 2023). One approach is to leverage a mixture-of-experts framework, where a gating mechanism determines which expert retriever to utilize for a given test query (Kasela et al., 2024; Lee et al., 2024). However, these methods rely on predefined expert retrievers that are trained offline with prior domain knowledge and specific domain boundaries. As a result, they may struggle to adapt to dynamically evolving corpora due to the difficulty in determining the right time to introduce new experts for emerging content. Another approach is to continually learn the generative retriever model in evolving corpora (Chen et al., 2023). However, continuously updating the retriever for every new corpus is computationally expensive and may lead to overfitting on well-generalized documents, potentially reducing overall generalization ability.

To address this challenge, we propose a novel practical task of *predicting out-of-domain documents and corpus before indexing* for a given dense retriever. This task is critical for maintaining retrieval systems effectively, as the OOD corpus can indicate when retriever updates are needed. By identifying the OOD corpus before indexing, we can take preventive measures to enhance the retrieval performance at inference time. For instance, we can select the most suitable retriever or timely

update the retriever in use for the OOD corpus. To achieve this, we introduce **GradNormIR**, an unsupervised approach for detecting OOD documents within a corpus without requiring queries. In image classification tasks, Huang et al. (2021); Xie et al. (2024) have demonstrated that gradient norms can effectively detect OOD images and estimate test-time accuracy without labeled data. Inspired by this insight, we leverage the gradient norm of the contrastive loss as an unsupervised estimator of a retriever’s generalizability on a given corpus. Moreover, we employ novel sampling strategies to assign positive and negative instances for contrastive loss.

We evaluate our method on the BEIR benchmark (Thakur et al., 2021), comprising multiple diverse datasets across multiple domains. First, we demonstrate that GradNormIR effectively detects OOD documents that are likely to cause retrieval failures. Next, we show that GradNormIR can select the most suitable retriever using only the document corpus, without queries. Finally, we simulate evolving document corpora using the BEIR by introducing datasets sequentially, and demonstrate how GradNormIR enables efficient retriever updates while maintaining performance. Our experiments validate both the importance of OOD detection for retrieval systems and GradNormIR’s effectiveness in adapting to evolving corpora.

In summary, our contributions are as follows:

1. We introduce a novel task of predicting OOD corpus before indexing, enabling efficient and effective retriever updates in evolving corpora.
2. We propose GradNormIR, an unsupervised method leveraging gradient norms and novel sampling strategies to detect OOD documents and predict OOD corpus without gold queries.
3. Our experiments with three practical use cases on the BEIR benchmark demonstrate both the necessity of the proposed task for a robust retrieval system and the effectiveness of GradNormIR.

## 2 Related Work

**Information Retrieval.** Recent advancements in text embeddings have significantly transformed the field of IR, particularly with the rise of dense retrievers. The success of these models has primarily been driven by the availability of large training datasets such as NQ (Kwiatkowski et al., 2019),

MS-MARCO (Bajaj et al., 2016), HotpotQA (Yang et al., 2018), and NLI (Gao et al., 2021). A notable example is DPR (Karpukhin et al., 2020), which employs a dual-encoder mechanism for open-domain question-answering, where questions and passages are independently embedded.

In addition, unsupervised methods have also gained prominence for improving the generalization of dense retrievers. Contriever (Izacard et al., 2022) enlarges a pre-training dataset using unsupervised data augmentation for contrastive learning. Similarly, E5 (Wang et al., 2022) leverages weak supervision to create a large-scale dataset (CCPairs) using a consistency-based filter. Recently, hybrid approaches like BGE-M3 (Chen et al., 2024) combine dense, sparse, and multi-vector retrieval strategies through self-knowledge distillation.

**OOD Robustness.** In IR, OOD robustness refers to a model’s ability to maintain performance when exposed to documents that deviate from the distribution of its training data. One of the most widely used benchmarks is the BEIR (Thakur et al., 2021), consisting of diverse retrieval tasks across multiple domains. Using BEIR, Chen et al. (2022) demonstrate that dense retrievers perform poorly on OOD datasets compared to traditional lexical retrievers like BM25. In response, they propose a hybrid model that integrates both types of models, showing robust performance in zero-shot retrieval. Similarly, Yu et al. (2022) report that distribution shifts cause a noticeable decline in zero-shot accuracy in dense retrievers.

Several strategies have been studied to improve OOD performance on unseen documents. Data augmentation using contrastive learning has shown promising results (Wang et al., 2021; Izacard et al., 2022). Some methods modify architectures to enhance generalizability; mixture-of-experts frameworks (Kasela et al., 2024; Lee et al., 2024) and multi-head RAG models (Besta et al., 2024) adapt retrieval strategies according to domains. Also, Khramtsova et al. (2023) investigate how to select the most suitable in zero-shot search, and Khramtsova et al. (2024) suggests to rank dense retrievers using LLM-generated pseudo queries. On the other hand, some current works propose continual learning methods to handle dynamic corpora without forgetting previously learned information. For example, memory-based methods (Cai et al., 2023) maintain backward compatibility with existing document embeddings, while incremental indexing (Chen et al., 2023) updates document in-

dices of generative retrievers to handle both new and previously indexed documents.

However, few have explored which documents are OOD from the perspective of the dense retriever models. Layer-wise score aggregation (Darin et al., 2024) combines anomaly scores from each encoder layer to get a more accurate anomaly score, enhancing overall robustness. However, this model centers on text classification, whereas our work focuses on evaluating the generalizability of different dense retriever models.

### 3 Problem Statement

#### 3.1 OOD Robustness in IR

The OOD robustness refers to a model’s ability to perform effectively when confronted with data that deviates from the training distribution. In IR, for a dense retriever  $f_\theta$  trained on  $\mathcal{D}_{train}$  drawn from the original distribution  $\mathcal{G}$ , it can be defined as follows:

$$|\mathcal{R}_M(f_\theta; \mathcal{D}_{test}, K) - \mathcal{R}_M(f_\theta; \tilde{\mathcal{D}}_{test}, K)| \leq \delta$$

where  $\mathcal{D}_{train}, \mathcal{D}_{test} \sim \mathcal{G}, \tilde{\mathcal{D}}_{test} \sim \tilde{\mathcal{G}}.$  (1)

$\mathcal{R}_M(f_\theta; \mathcal{D}, K)$  denotes a ranking metric for the top- $K$  results by  $f_\theta$ , and  $\delta$  is an acceptable error threshold. Note that a test dataset  $\mathcal{D}_{test}$  is drawn from original  $\mathcal{G}$  and a new test dataset  $\tilde{\mathcal{D}}_{test}$  is from a new distribution  $\tilde{\mathcal{G}}$ . If the retriever  $f_\theta$  satisfies Eq.(1), it is considered  $\delta$ -robust against OOD data for metric  $M$  (Liu et al., 2024).

The OOD robustness in IR is typically categorized into two aspects: robustness to unseen queries and unseen documents. In this work, we focus on the robustness to unseen documents, since our key challenge is how to deal with evolving corpora for dense retrievers.

#### 3.2 The OOD Document and Corpus

We aim to predict whether a given corpus  $\mathcal{C}$  is an OOD corpus. The likelihood of  $\mathcal{C}$  being OOD for a given retriever  $f_\theta$  can be represented by the proportion of OOD documents in  $\mathcal{C}$  as follows:

$$r(\mathcal{C}) = \frac{|\tilde{\mathcal{C}}|}{|\mathcal{C}|}, \text{ with } \tilde{\mathcal{C}} = \{d \in \mathcal{C} | d \text{ if } \mathcal{M}(d; f_\theta, \mathcal{C})\}.$$

$\mathcal{M}(d; f_\theta, \mathcal{C})$  is an algorithm that returns 1 if  $d$  is detected as an OOD document. The given corpus  $\mathcal{C}$  can be classified as an OOD corpus if  $r > \gamma$ , where  $\gamma$  is a threshold.

The definition of an OOD document  $d$  is as follows. If  $(q, d)$  is a correct query-document pair

with  $d$  in a new corpus  $\mathcal{C}$  and the retriever fails to fetch  $d$  for the query  $q$ , then  $d$  is an OOD document:  $\{d \in \mathcal{C} | d \notin f_\theta(q, \mathcal{C})\}$ . That is, the retriever does not generalize with  $d$ . The algorithm  $\mathcal{M}$  aims to find such documents as many as possible for a novel corpus. Our proposed  $\mathcal{M}$  in Section 4 is *unsupervised* in that gold pairs  $(q, d)$  are not required for the algorithm but used only for evaluation purpose.

## 4 Approach

We first discuss how prior work utilizes the gradient norm in image classification. We then propose GradNormIR, an unsupervised approach for detecting OOD documents in a corpus to decide whether the corpus is OOD without gold queries.

### 4.1 Preliminary of Gradient Norm

Previous studies have leveraged the gradient norm in predicting model performance in image classification. GradNorm (Huang et al., 2021) uses the gradient norm to estimate uncertainty for OOD images. They assume that if the model performs well, it exhibits high confidence in its predictions, causing the softmax output to deviate significantly from a uniform distribution. To quantify this, it computes the KL divergence between the softmax output and a uniform distribution, and then calculates the resulting gradient norm. They identify a small gradient norm as indicative of OOD. GDScore (Xie et al., 2024) is an unsupervised test-time accuracy estimation method to predict a classifier’s accuracy without gold labels. GDScore pseudo-labels the class of a given input to compute the cross-entropy loss and then uses the gradient vector norm of the last layer as an accuracy estimator.

Unlike previous studies, our method utilizes the gradient norm to predict OOD corpus in IR. To accomplish this, we introduce novel positive and negative sampling strategies for computing the gradient norm of the contrastive loss.

### 4.2 GradNormIR

We use the gradient norm to detect OOD documents in a corpus. To get the gradient norm, we need to calculate the loss. Dense retrievers are usually trained with InfoNCE loss, defined as

$$\mathcal{L}_{\text{InfoNCE}} = -\log \frac{e^{s(q, d^+)/\tau}}{e^{s(q, d^+)/\tau} + \sum_{i=1}^N e^{s(q, d_i^-)/\tau}},$$

where  $s(q, d) = \cos(f_\theta(q), f_\theta(d))$  is the cosine similarity between query  $q$  and document  $d$ .  $f_\theta(\cdot)$

is the last hidden layer’s output, and  $\tau$  is a temperature parameter.

When a new corpus  $\mathcal{C}$  is given, user queries are not yet available, making it challenging to compute the gradients. Therefore, we consider each document  $d$  as a query and assign pseudo-labels of positives and negatives to other documents  $\mathcal{C} \setminus \{d\}$  that are relevant or irrelevant with  $d$ , respectively. Instead of using external trained models for such labeling, we obtain pseudo-labels directly from the retriever’s own internal similarity scores.

**Query Representation with Dropout.** As discussed, every  $d$  is regarded as a document query. To better reflect the retriever’s generalizability in the gradient norm, we introduce perturbations to the representation of  $d$ . Following Jeong et al. (2022), we apply stochastic dropout to randomly mask some parts of  $d$ ’s representation  $f_\theta(d)$ . If  $f_\theta(d)$  generalizes well to  $d$ , masking some tokens in its embedding has little impact on selecting its positive and negative samples. Otherwise, it can lead to big shifts in the embedding space, potentially selecting wrong positive and hard negative samples and causing a large gradient norm.

Specifically, we first encode the document query with the last hidden state  $h = f_\theta(d)$ . We then randomly mask the hidden state; the mask  $m$  is sampled from a Bernoulli distribution:

$$h' = h \odot m, \text{ where } m \sim \text{Bernoulli}(p),$$

where  $\odot$  denotes element-wise multiplication. Finally, we obtain the perturbed document query  $d'$  by applying pooling on  $h'$ .

**Positive and Negative Pool.** Before obtaining positive and negative samples w.r.t  $d$ , we first split the documents  $\mathcal{C} \setminus \{d\}$  into two pools using the  $k$ -nearest neighbors ( $k$ -NN). For a given document  $d$ , we retrieve the top  $k$  related documents from  $\mathcal{C}$  using the perturbed query  $d'$ , resulting in a set  $D^+(d)$ , which is considered a positive pool. The set of all the other documents,  $\mathcal{C} \setminus D^+(d)$ , is treated as negative pool  $D^-(d)$ . We set  $k$  to be a relatively high value (e.g., 100) to increase the likelihood that relevant documents are in the positive pool.

**Sampling Strategies.** For more precise positive samples for loss computation, we take the top- $p$  documents  $\{d_1^+, \dots, d_p^+\}$  from the positive pool  $D^+(d)$ , where  $p \ll k$ . For negative sampling, previous work (Zhan et al., 2021) has shown that using hard negative samples can improve performance, as they share similar content but are not

Figure 2: Dropout for the document query representation along with positive and hard negative sampling.

directly relevant to the given query. Thus, we adopt a hard negative sampling strategy rather than random negatives. For each positive  $d_i^+$ , we find top- $n$  nearest documents  $\{d_{i1}^-, \dots, d_{in}^-\}$  from the negative pool  $D^-(d)$ . These documents are considered hard negatives since they are similar to the positives of  $d_i^+$  but still irrelevant to  $d$  since they are from  $D^-(d)$ . If  $f_\theta$  is well-generalizable on  $d$ ,  $f_\theta$  is likely to differentiate positive samples with hard negative samples, leading to a small gradient norm (i.e., little need for retriever update); otherwise, it may produce a large gradient norm.

**Gradient Norm.** Finally, we compute the gradient of  $d$  using the derivative of the loss with respect to the parameters  $\theta$  of the retriever encoder:

$$\nabla \mathcal{L}_\theta = -\nabla_\theta \log \frac{e^{s(d, d_i^+)/\tau}}{e^{s(d, d_i^+)/\tau} + \sum_{j=1}^n e^{s(d, d_{ij}^-)/\tau}},$$

where  $d_i^+$  is one of the positive sample and  $d_{ij}^- \in D^-(d_i^+)$  are its corresponding hard negative samples. This gradient measures the retriever’s sensitivity to the parameter changes when applied to the positive sample  $d_i^+$ . Finally, the average gradient norm across all positive samples  $\{d_i^+\}_{i=1}^p$  is

$$\text{GradNormIR} = \frac{1}{p} \sum_{i=1}^p \|\nabla_\theta \mathcal{L}\|_2, \quad (2)$$

where  $\|\cdot\|_2$  denotes the  $\mathcal{L}_2$ -norm. This average gradient norm serves as a measure of the retriever’s generalizability on  $d \in \mathcal{C}$ . A higher value indicates a greater sensitivity and potentially less stability when adapting to  $d$ . Please refer to Appendix B for detailed proof.

**Predicting OOD Documents.** Our algorithm predicts  $d$  as an OOD document if its gradient norm is sufficiently large. The threshold can be decided based on the gradient norms of in-domain documents, with the median chosen for its robustness to outliers. Since gradient norms vary across documents, the median provides a stable threshold, minimizing the impact of extreme values. If the gradient norm is larger than the median value, we detect  $d$  as an OOD document.

## 5 Experiments

We conduct three sets of experiments to evaluate our approach. First, we show that our GradNormIR effectively identifies OOD documents in a given corpus. Next, we make sure that GradNormIR’s OOD detection is useful in selecting the most suitable retriever, even without any queries. Finally, in evolving corpora, we demonstrate that GradNormIR enables efficient continuous retriever updates by selectively retraining it only on the predicted OOD corpus. We also present an ablation study for several hyperparameters in Appendix F.

### 5.1 Experimental Setup

**Dense Retrievers.** We evaluate several state-of-the-art dense retriever models, including BGE (Xiao et al., 2023), Contriever (Izacard et al., 2022), E5 (Wang et al., 2024), and GTE (Li et al., 2023b).

**Dataset.** The BEIR benchmark (Thakur et al., 2021) provides a diverse collection of datasets for evaluating retriever models across multiple domains. From the 19 available datasets, we exclude those used for fine-tuning the tested retrievers models (e.g., MSMARCO, Natural Questions, FEVER, HotpotQA, CQADupStack), as well as those that are no longer accessible (e.g., TREC-News, Robust04, Signal-1M, BioASQ), following Khramtsova et al. (2023). This leaves us with 10 datasets for evaluation. Each dataset consists of a document corpus and query-document pairs. In our experiment, we define the corpus  $\mathcal{C}$  as the set of documents with at least one annotated relevant query, ensuring a quantitative evaluation.

**Baselines.** We compare our method with three baselines: (i) **Layerwise** (Izacard et al., 2022): unsupervised textual OOD detection via layerwise anomaly scores (e.g., negative cosine similarity), (ii) **IPQ** (Chen et al., 2023): incremental production quantization with clustering, and (iii) **Gen-Query** (Khramtsova et al., 2023): zero-shot ranking using pseudo-questions generated by large language models.

**Hyperparameters.** To calculate the gradient norm for each document  $d$ , we set the dropout rate to 0.02 and the number of positives ( $p$ ) to 8. We use four negative samples ( $n$ ) to reduce the computational cost. For OOD detection, we use the average gradient norm of 3,000 in-domain Natural Questions (NQ) documents (Kwiatkowski et al., 2019) as the reference threshold, since all test retrievers are already trained on NQ. Documents with gradi-

Table 1: Comparison of OOD document detection across different retriever models on the BEIR benchmark. A lower Document Retrieval Rate value, defined in Eq.(3), indicates more accurate OOD detection.

ent norms exceeding this average are classified as OOD. We set the OOD corpus prediction threshold ( $\gamma$ ) to 0.5. We experimentally set this value based on the retriever’s performance. We conduct an extensive ablation study as described in Appendix F, exhibiting the robustness of our approach.

## 5.2 Detection of OOD Documents

This task aims to detect OOD documents from a new document corpus  $\mathcal{C}$ . Our method selects OOD documents where GradNormIR exceeds the threshold as described in Section 5.1. For other baselines, we rank the documents in descending order by their OOD scores as described below, and then select the same number of top-ranked documents as GradNormIR for fairness. Finally, we compare these detected OOD documents using their retrieval rate using query-document pairs in the dataset.

**Evaluation Metric.** To evaluate the OOD document detection, we use the document retrieval rate (DRR). As described in Section 3.2, the effectiveness of an approach can be measured using how poorly detected OOD documents are retrieved to relevant queries. For each dataset, we organize annotations as  $\{d_i, Q_{d_i}\}_{i=1}^N$ , where  $Q_{d_i}$  represents the set of relevant queries for each document  $d_i$ . DRR is then calculated as

$$\text{DRR} = \frac{\sum_{d_i \in \mathcal{C}} \sum_{q_{d_i} \in Q_{d_i}} \mathbb{1}\{d_i \in D^+(q_{d_i})\}}{\sum_{d_i \in \mathcal{C}} |Q_{d_i}|}, \quad (3)$$

where  $\mathbb{1}$  is an indicator function that returns 1 if  $d_i$  appears in the top- $k$  retrieval results  $D^+(q_{d_i})$  (with  $k = 100$ ), and 0 otherwise. Lower DRR

values indicate that the OOD documents are more successfully identified.

**Baselines.** For each baseline, we first compute the OOD score of each document  $d$  as follows: (i) **Layerwise**: we compute the negative cosine similarity between latent vectors of  $d$  and in-domain documents across all layers and aggregate them to produce a final OOD score for  $d$ . (ii) **IPQ** creates quantization codebooks from  $\mathcal{C}$  to get centroids. We quantize all representations to generate centroids and use the average Euclidean distance between the quantized representation and the centroids as the OOD score of  $d$ . (iii) **GenQuery**: we generate a pseudo-question  $\hat{q}$  for  $d$  using Llama3.1-8B. We then use the rank of  $d$  in the retrieval results of  $\hat{q}$  as the OOD score.

### 5.2.1 Results

Table 1 presents the results of OOD document detection across 10 datasets of the BEIR benchmark. Our GradNormIR consistently outperforms the baselines, achieving the lowest average DRR on all tested retrievers. Notably, GradNormIR shows significant drops on DBPedia-Entity and Scidocs (e.g., reductions of 28.18 and 15.36 for BGE).

In the baselines, the detected OOD documents often show unexpectedly higher retrieval rates than the average DRR of all documents, indicating wrong detection. For instance, GenQuery in DBPedia-Entity shows significant increases across all retrievers, although it achieves the best performance on Quora for Contriever, E5, and GTE. Also, in Climate-FEVER, GenQuery increases for BGE, E5, and GTE. This may be because these docu-

| Method    | ArguAna      | C-FEVER      | DBPedia      | FiQA         | NFCorpus     | Quora        | Scidocs      | SciFact      | COVID        | Touché       |

| IPQ       | 99.00        | 79.14        | 85.45        | 77.25        | 28.88        | <b>99.97</b> | 59.06        | 98.39        | 18.53        | 97.16        |
| GenQuery  | 99.00        | 79.14        | 85.45        | 77.25        | 28.88        | <b>99.97</b> | 59.06        | 98.15        | 18.53        | 97.16        |
| Ours      | <b>99.36</b> | <b>82.55</b> | <b>89.73</b> | <b>78.51</b> | <b>35.73</b> | <b>99.97</b> | <b>69.63</b> | <b>99.73</b> | <b>21.52</b> | <b>98.40</b> |
| Oracle    | 99.43        | 82.92        | 89.73        | 83.25        | 35.73        | 99.97        | 69.98        | 99.73        | 21.52        | 99.23        |

Table 2: Results of zero-shot retriever selection in terms of Recall@100 scores of the retriever selected by each OOD method. The *oracle* is the upper bound, indicating the performance of the actual best retriever per dataset.

ments are also out-of-domain to the LLM. Typically, IPQ and Layerwise baselines show the lowest DRRs in some cases, but their performance fluctuates up and down, indicating low robustness.

Overall, GradNormIR consistently shows lower document retrieval rates for detected OOD documents, demonstrating that it accurately identifies OOD documents across datasets. We further evaluate the OOD documents ratio,  $r(\mathcal{C})$  in Section 3.2 in the following experiments.

### 5.3 Best Retriever Selection

This task predicts the most suitable dense retriever from a set of retrievers given a corpus  $\mathcal{C}$ , i.e., it selects the retriever with the highest generalizability for the given  $\mathcal{C}$  using the OOD detection method. This task shows that our approach is helpful for selecting not only when the retrievers are updated but also which one is the best in the stream of corpora.

**Setup.** We select one of four retrievers (as described in Section 5.1), choosing the one that has the lowest OOD document ratio,  $r(\mathcal{C})$ . Specifically, given a test dataset including  $\mathcal{C}$  and query-document pairs, we calculate  $r(\mathcal{C})$  for each retriever. Next, we select the retriever with the lowest  $r(\mathcal{C})$ . Then, we evaluate the selected retriever on the query-document pairs. For each dataset, we report the Recall@100 performance of the retriever selected by each baseline.

**Baselines.** To calculate  $r(\mathcal{C})$ , we first compute the OOD score of the in-domain NQ documents for each baseline in the same way as in Section 5.2. Then, we calculate the ratio of documents with an OOD score greater than the median. In this way, we can compute  $r(\mathcal{C})$  of each baseline.

#### 5.3.1 Results

Table 2 presents the Recall@100 performance of the selected retriever by each baseline. The *oracle* row shows the performance of the actual optimal retriever on each dataset. The retriever chosen by GradNormIR consistently achieves the highest performance across datasets. Although our method does not always choose the top-performing

retriever (e.g., BGE for ArguAna and GTE for FiQA), it accurately identifies the second-best retriever (GTE for ArguAna and BGE for FiQA) at least. These results show that GradNormIR is highly effective in selecting the most appropriate retriever based solely on the given document corpus, even before any queries are introduced.

### 5.4 Continual Updates

The goal of this task is to update the retriever only when an OOD corpus is given, balancing performance stability and computational cost in evolving corpora.

**Setup.** We simulate the sequential streaming of a corpus using datasets of the BEIR coming in alphabetical order. For instance, in session  $S_1$ , the Arguana corpus is given, in session  $S_2$ , the ClimateFEVER corpus is given, and so on. We continually update Contriever using RecAdam optimizer (Chen et al., 2020), widely employed to mitigate the language model’s catastrophic forgetting. In session  $S_t$ , we update the current retriever with a given corpus. We then build a retrieval index using corpus from  $S_1$  to  $S_t$ . Finally, we evaluate the retriever with queries from  $S_1$  to  $S_t$ . For training details, please refer to Appendix A.

**Baselines.** We test three types of baselines: (i) Zero-shot: the retriever remains fixed with no further updates. (ii) Selective: the retriever is updated only when a newly given corpus is determined as an OOD corpus. (iii) Naïve: the retriever is updated whenever a new corpus is given, common in continual learning. For selective retraining, in each session  $S_t$ , we decide whether to update the retriever and use the most recently updated retriever to build an index using corpus from  $S_1$  to  $S_t$ . We evaluate different update strategies from the four baselines. In GradNormIR, we update the retriever when a corpus is OOD, in total  $N$  times ( $N = 6$ ). For the other retraining methods, the retriever undergoes the same  $N$  updates with the corpora of the highest OOD ratios for fairness.

**Metrics.** We compute the average Recall@100

Figure 3: Average of Recall@100 across  $S_1$  to  $S_t$  with respect to the upper bound for each dataset using a single-trained retriever. Although the trend decreases due to the expanding document corpus over sessions, performance remains robust with continual updates.

in each session  $S_t$ , computed as the mean Recall@100 of the datasets from  $S_1$  to  $S_t$ . We report the relative performance with respect to an upper bound per dataset, since each dataset has different levels of difficulty. The upper bound of each dataset is the Recall@100 value of the retriever fine-tuned only with the dataset.

#### 5.4.1 Results

Figure 3 illustrates the retrieval results of different continual update strategies over the sessions. Overall, performance degrades as the sessions progress. This occurs because as the number of documents increases, the corpus expands, making it more difficult to retrieve the correct documents. Thus, the performance of the Zero-shot baseline quite drops to around 80. However, with continual updates, the other baselines maintain stable performance around 90, preventing catastrophic forgetting.

Initially, GradNormIR exhibits lower performance in  $S_1$  and  $S_2$ , since the retriever is not updated. Nonetheless, it does not show significant degradation afterward, maintaining the retriever’s accuracy by retraining in later sessions. Starting from session  $S_6$ , GradNormIR achieves the highest average performance among all baselines. Notably, in  $S_6$ , GradNormIR outperforms even the Naïve baseline, which retrains the retriever in every session. This demonstrates that unconditional retraining leads to task performance degradation when not necessary. The performance gap persists until the final session, demonstrating the efficiency and effectiveness of GradNormIR’s selective retraining.

Conversely, all other selective baselines exhibit lower performance than Naïve baseline. For in-

| Hard Neg | Dropout | DRR (↓)      |              |              |              |
|----------|---------|--------------|--------------|--------------|--------------|
|          |         | BGE          | Cont         | E5           | GTE          |
|          | ✓       | 67.68        | 64.19        | 67.45        | <b>68.07</b> |
| ✓        |         | 65.79        | 62.41        | <b>65.58</b> | 70.75        |
| ✓        | ✓       | <b>65.03</b> | <b>61.46</b> | 65.59        | 68.62        |

Table 3: Ablation study on the impact of dropout for document queries and the use of hard negatives.

stance, Layerwise displays robust performance in the earlier sessions, but it shows persistent performance degradation in later sessions since it is not trained on the OOD corpus in  $S_4$  and  $S_6$ . This suggests that selective retraining only with OOD corpus can ensure the maintenance of retriever performance in evolving corpora.

#### 5.5 Ablation Study

We evaluate the impact of the dropout and the use of hard negatives. Table 3 displays the results of the average DRR in OOD document detection. When both dropout and hard negatives are applied, the model achieves the best performance, particularly for the BGE and Contriever. For E5, hard negatives contribute to an increase in DRR, while dropout also proves effective. Conversely, for GTE, hard negatives enhance performance, whereas dropout leads to performance degradation. This suggests that the optimal setting may vary depending on the chosen retriever. Nonetheless, even in these two cases, neither hard negatives nor dropout perform poorly. Additional ablation experiments are provided in Appendix F.

### 6 Conclusion

We introduced the novel task to predict OOD corpus for a given dense retriever before indexing, a critical challenge for ensuring its robust performance in dynamic, ever-evolving corpora. To achieve this, we proposed GradNormIR as an unsupervised method that leverages gradient norms of the contrastive loss to detect OOD corpus. With novel sampling strategies, including document-to-document retrieval with positive and hard negative sampling, GradNormIR could predict corpus that a retriever is likely to fail before querying begins. We can select the most suitable dense retriever for a given a corpus or update a retriever in a timely manner in evolving corpora. One intriguing future work could focus on online prediction of an OOD document, where individual document arrives continuously rather than as a complete corpus.

## Limitations

While this work underscores the importance of predicting OOD documents and corpus, there may be some potential limitations. As we focus on identifying these documents, performance may still degrade due to unseen queries at inference time. Expanding the framework to handle such queries could enhance its robustness in real-world scenarios. Additionally, the method’s reliance on document-to-document retrieval may introduce challenges when handling extremely large corpus, where efficient scaling could become a concern. In this case, it may be necessary to divide the corpus into smaller, more manageable chunks for processing.

## Ethics Statement

This research does not raise any ethical concerns, as it primarily focuses on the technical development of information retrieval models and their evaluation. The methods proposed are intended for improving document retrieval performance in non-sensitive, general-purpose datasets, without handling personal, confidential, or otherwise ethically sensitive data.

## A Experiment Details

**Models.** In experiments, we use four dense retrievers: BGE-large-en-v1.5, unsupervised Contriever, multilingual E5 large, and GTE-base. In hugging face, the model names are *BAAI/bge-large-en-v1.5*, *facebook/contriever*, *intfloat/multilingual-e5-large*, and *thenlper/gte-base*, respectively.

**GradNormIR.** For contrastive loss temperature  $\tau$ , we use 0.05 for all baselines but 0.01 for e5. The probability distribution is skewed for E5, as noted in hugging face; setting the temperature to 0.05 does not make the model compute contrastive loss effectively.

For positive and negative sampling, we sample 8 positive samples ( $p$ ) and four negatives ( $n$ ) for each positive. As sampling 4 negatives per positive is traditional, we follow previous work.

For the dropout, we use 0.02, which means 2 percent of tokens are masked to zero. For the other experimental setups, we follow the default values of BAAI Flagembeddings<sup>1</sup>.

We conduct ablation studies on the impact of the number of positive samples and dropout rate in Section F.2.

**GenQuery.** We use Llama3.1 8B with Q4\_0 quantization to generate pseudo queries with the temperature set to 0.5 and the max\_new\_tokens set to 256. Also, the prompt template is shown in Figure 4.

**IPQ.** For production quantization, we set the number of quantization groups as 8, which means the last hidden state after pooling (e.g., 1024 dimensions) is divided into 8 groups (e.g., 128 dimensions for each group), and each is clustered using KMeans. We set the number of clusters as 16, which means each 128-dimensional vector becomes an integer between 0 and 15.

**Continual Updates.** For the training dataset, we use generated queries from the Hugging Face BEIR repository to retrain the retriever, as original test queries in the BEIR are used in the evaluation. Using these queries, we perform supervised fine-tuning. We set epoch to 4, gradient\_accumulation\_steps to 256, batch\_size to 4, learning\_rate to 1e-04, lr\_scheduler to "Constant", with multi-GPU (4 GPUs) parallelization.

**Resources.** To run GradNormIR, we use one NVIDIA TITAN RTX 24GB GPU for about 6 hours per dataset on average. Running the GenQuery baseline on the same GPU takes 16 hours

per dataset.

## B Theoretical Analysis

The gradient norm in our method measures how well the model’s embeddings align with its self-generated pseudo labels. It reflects the model’s confidence and correctness in distinguishing between positive and negative samples based on its own embeddings. In this section, we analyze the method theoretically to further clarify the behavior of the gradient norm and its implications for model generalization.

In contrastive learning, the model’s parameters are updated based on the gradients with respect to all embeddings involved in the loss, including the anchor document  $E_D(d)$ , the positive sample  $E_D(d^+)$ , and the negative samples  $E_D(d_i^-)$ . However, we simplify the analysis by primarily focusing on the gradient with respect to  $E_D(d)$ , as the gradients of other embeddings are small enough to be negligible. We define the probability of a document  $d'$  (either  $d^+$  or  $d_i^-$ ) as

$$p_{d'} = \frac{e^{s(d,d')/\tau}}{e^{s(d,d^+)/\tau} + \sum_i e^{s(d,d_i^-)/\tau}}. \quad (4)$$

Then, the gradient norm of the loss with respect to  $E_D(d)$  is

$$\|\nabla \mathcal{L}\| = \frac{1}{\tau} \left\| (1 - p_{d^+}) E_D(d^+) - \sum_i p_{d_i^-} E_D(d_i^-) \right\|. \quad (5)$$

To examine this further, assume there is only one negative sample, reducing the gradient norm to

$$\|\nabla \mathcal{L}\| = \frac{1}{\tau} (1 - p_{d^+}) \|E_D(d^+) - E_D(d^-)\|. \quad (6)$$

The likelihood  $p_{d^+}$  can be expressed as:

$$p_{d^+} = \frac{1}{1 + e^{-\Delta s_i/\tau}}, \quad (7)$$

where  $\Delta s_i = s(d, d^+) - s(d, d^-)$  measures the similarity difference between the anchor document and its positive and negative counterparts.

In cases where an OOD or non-generalizable document query is given, the similarity  $s(d, d^+)$  tends to be low, making  $p_{d^+}$  small and thereby increasing the gradient norm in Eq. (6). Similarly, when  $\Delta s_i$  is small, the model struggles to differentiate between the positive and negative samples, causing the gradient norm to rise. This pushes the

<sup>1</sup><https://github.com/FlagOpen/FlagEmbedding>

Generate one Q&A pair based on a given context, where the context is understood but NOT DIRECTLY VISIBLE to the person answering the question. The question should cover the main focus of the full context. Assume the person answering the question has common sense and is aware of the details and key points in the sentence(s), but the sentence(s) itself is not quoted or referenced directly.

Sentence(s) : {paragraph}  
 Use the following instructions for generating a Q&A pairs:  
 1) Provide one {question}{answer}  
 2) DON'T use phrases such as 'according to the sentence(s)' in your question.  
 3) DON'T use phrases in the context verbatim.  
 4) An answer should be an entity or entities.  
 5) Ensure the question can be answered without referring back to the document, assuming domain knowledge.  
 6) Ensure the question includes enough context to be understood on its own.  
 7) The question should be general enough to be answerable by someone familiar with the topic, not requiring specific details from the context.  
 8) If there is not enough information to generate a question, state 'Not enough information to generate a question.'

Be sure to follow the following format and provide a question and answer pair within curly brackets.

The format is as follows: {Question}{Answer}

Figure 4: The prompt template to create pseudo queries using Llama3.1 8B in zero-shot. We prompt it to generate a question along with a corresponding answer to ensure the question can be answered. We use only generated question for evaluation.

model to adjust its embeddings to improve generalization. This signifies that the gradient norm acts as an indicator of the model’s confidence in its pseudo labels. A large gradient norm suggests uncertainty or misalignment in the model’s representations, indicating OOD or less generalizable documents.

## C Feasibility of GradNormIR

We aim to validate whether GradNormIR can identify the documents that are difficult for the the models to retrieve. To this end, we inspect if there is a consistent relationship between the computed gradient norm and the likelihood of a document successfully retrieved by its associated queries.

**Evaluation Metric.** To evaluate the effectiveness, we measure the document-to-query (d2q) as the standard metric. In each dataset, annotations are provided in the form of  $\{q_i, D_i\}_{i=1}^N$ , where  $q_i$  is a query and  $D_i$  is the set of relevant documents. We reorganize these annotations as  $\{d_i, Q_i\}_{i=1}^N$ , where  $Q_i$  represents the set of relevant queries for each document  $d_i$ . For a document to be considered effectively retrievable, it should be retrieved for all its relevant queries.

To quantify this, we define the d2q recall as follows:

$$\text{recall}_{\text{d2q}} = \frac{\sum_{q_i \in Q_i} \mathbb{I}\{d_i \in D^+(q_i)\}}{|Q_i|}, \quad (8)$$

where  $\mathbb{I}$  is an indicator function and  $D^+(q_i)$  represents the top- $k$  retrieved documents (with  $k =$

100).

When the retriever model generalizes well for a document  $d_i$ , the d2q recall value will be high. Additionally, if the retriever generalizes effectively on  $d_i$ , the gradient norm associated with  $d_i$  will be low, as the retriever does not need to make substantial updates based on the contrastive loss for  $d_i$ . Therefore, there should be an inverse relationship: higher the d2q recall values correspond to lower the gradient norms.

**Results.** Figure 5 illustrates the relationship between GradNormIR and d2q recall. We divide the data points into quartiles based on GradNormIR values, sorted in ascending order and labeled as Q1, Q2, Q3, and Q4. The x-axis represents these quartiles, while the y-axis shows the average d2q recall for each group.

The results reveal a strong inverse correlation between GradNormIR and retrieval performance. As GradNormIR values increase from Q1 to Q4, d2q recall decreases. This indicates that higher GradNormIR values (Q4) are associated with documents that are more challenging for the retriever to retrieve consistently. Conversely, lower GradNormIR values (Q1) correspond to higher recall, indicating better retrieval performance. When d2q recall approaches 1, such as Quora and SciFact, this trend becomes less noticeable. This is likely because the datasets have been trained on; nearly all documents are well generalized and easily retrievable.

Figure 5: Feasibility results of GradNormIR for several recent retrievers on the BEIR benchmark. The x-axis shows quartiles of GradNormIR, sorted in ascending order (Q1 to Q4), while the y-axis represents the d2q recall@100, averaged across documents within each quartile. The results show that GradNormIR can predict retrieval performance; lower GradNormIR values (Q1) generally lead to better retrieval outcomes across most datasets. As GradNormIR increases (Q4), the d2q recall decreases.

Figure 6: Results of relevance gains via OOD document filtering.

## D Relevance Gains via Filtering

To evaluate the impact of OOD documents, we also conduct a document filtering experiment. Specifically, we remove OOD documents from the given corpus  $\mathcal{C}$ , thereby enhancing retrieval relevance.

**Setup.** For each dataset, we begin with an evaluation set  $\{(d_i, Q_i)\}_{i=1}^N$ . If  $d_i$  is detected as an OOD document, we remove it from the evaluation set, meaning we no longer evaluate  $d_i$  as a gold label for its associated queries  $q_i \in Q_i$ . We then evaluate the performance on the test queries  $\{Q_i\}_{i=1}^N$ . By removing such OOD documents, we aim to exclude irrelevant or misleading texts that could otherwise confuse the retriever, thereby potentially improving retrieval performance. We measure retrieval performance using Recall@100, following Izacard et al. (2022).

Figure 6 presents the total sum of gains in Recall@100 across 10 datasets of the BEIR after removing OOD documents. Our method, GradNormIR, demonstrates significant performance improvements across all retrievers. Specifically, it achieves gains of 34.73, 62.24, 51.15, and 12.40 points for BGE, Contriever, E5, and GTE, respectively. Even with GTE, where GradNormIR does not yield the best results, the overall retrieval enhancement remains the highest with our method.

## E Relation Between OOD Ratio and Performance

Figure 7 shows the relationship between OOD document ratio  $r(\mathcal{C})$  and retriever performance. The x-axis lists datasets in descending order of performance based on Contriever’s (Izacard et al., 2022) Recall@100. The y-axis represents the Non-OOD ratio  $(1 - r(\mathcal{C}))$ .

The graph’s descending trend indicates that  $1 - r(\mathcal{C})$  is proportional to retriever performance, as datasets with higher retrieval performance show greater Non-OOD ratios. GradNormIR clearly demonstrates this relationship, showing high Non-OOD ratios for Quora, Arguana, and Touché, and low ratios for FiQA, Scidocs, NFCorpus, and COVID. While GenQuery also exhibits a descending trend, it shows minimal variation from Quora to NFCorpus, making OOD corpus detection less effective.

To predict OOD corpora, we set  $\gamma$  to 0.5 based

Figure 7: Relation Between OOD Ratio and Performance

on the average performance across all datasets. With this threshold, we identify Scifact, Touch’e, DBPedia, FiQA, Scidocs, NFCorpus, and COVID as OOD corpora.

## F Ablation Study

We conduct additional ablation study of the impact of (i) the number of documents randomly sampled from the in-domain dataset and (ii) the number of positives in Eq. (2) as well as dropout rate.

### F.1 The Number of In-Domain Documents

Table 4 shows the results of DRR in predicting OOD documents, where the number of documents are determined by randomly selected 1,000 NQ documents, while Table 5 shows the results when 2,000 NQ documents are used for in-domain document samples. In both cases, our method show the lowest average DDR results for all models, indicating the robustness of GradNormIR in predicting OOD documents. Also, the number of documents detected as OOD are presented in Table 9. The number of OOD documents are lowest in GTE, as it can generalize to the datasets of the BEIR benchmark.

### F.2 The Number of Positives and Dropout Rate

The DRR results for the number of positives from 1 to 16 are shown in Table 10. As the number of positives increases, the DRR generally decreases because more gradient norm values make the method more robust. Additionally, when comparing the cases with and without dropout, the decrease is significantly higher as the number of positives increases. This is because the lower-ranking positives are more likely to be affected by dropout. However, when the dropout rate increases from 0.02 to 0.05, there are some cases where the filtered documents show higher DRR values, especially increasing 3.79 in an average of 16 samples for E5. This may be because excessive dropout can deteriorate model performance.

| Retriever  | Documents        | ArguAna      | C-FEVER      | DBPedia      | FiQA         | NFCorpus     | Quora        | Scidocs      | SciFact      | COVID        | Touché       | Avg (↓)      |

Table 10: Ablation study on the number of positives for computing GradNormIR in ( $p$  in Eq. (2)). The results present the DRR values of OOD documents prediction, comparing results without dropout and with dropout rates of 0.02 and 0.05 for the document query.
