Abstract

1 Large Language Models (LLMs) have recently been used to automate the causal
2 inference process by overcoming the expertise barrier. However, existing LLM-
3 powered approaches for causal effect estimation often require human users to
4 manually specify variables and methods, and those that do not require manual
5 specification support only a limited set of causal effect measures. To address
6 these limitations, we present Causal AI Scientist (CAIS), an LLM-augmented
7 causal tool with self-correction capabilities. Specifically, given a natural language
8 query and a dataset along with its description, CAIS uses LLMs to understand
9 the user query and dataset, and then selects a method based on a decision tree
10 approach. It then executes the selected method, applies a validation feedback loop
11 for self-correction, and uses the results to answer the input question, enabling fully
12 autonomous causal analysis. Extensive experiments across diverse queries curated
13 from textbooks, synthetic data, and real-world datasets demonstrate CAIS’s ability
14 to produce precise causal effect estimates through improved method selection and
15 self-corrections, while reducing runtime errors. We believe CAIS will serve as a
16 strong foundation for enabling fully automated causal inference with LLMs.

17 1 Introduction

18 Causal inference [Pearl, 2009, Imbens and Rubin, 2015] aims to quantify the effect of a treatment
19 or intervention on an outcome of interest. Understanding cause–effect relationships is central to
20 evidence-based decision-making in fields such as social science [Imbens, 2024], public health [Glass
21 et al., 2013], and biomedicine [Kleinberg and Hripesak, 2011]. Conducting rigorous causal analysis
22 typically requires methodological expertise, from selecting valid causal effect measures (i.e., esti-
23 mands) to choosing appropriate statistical methods, which limits accessibility for non-experts and
24 poses significant challenges to fully automating the causal inference pipeline. For instance, a policy
25 analyst with education and wage data may wish to estimate the effect of a job training program on
26 earnings but, without causal identification knowledge, could reach invalid conclusions.

27 Recently, Large Language Models (LLMs) have emerged as a solution to overcoming the expertise
28 barrier, as they can automate parts of the causal inference process using their extensive knowledge
29 across various domains [Kiciman et al., 2024]. Jiang et al. [2024a] have developed a specialized
30 foundational model, LLM4Causal, for causal inference and causal graph learning. Similarly, more
31 recent approaches have developed causal agents that leverage general-purpose foundational models
32 like GPT [OpenAI et al., 2024] to enable end-to-end performance of causal inference and learning
33 tasks [Wang et al., 2025, Han et al., 2024].

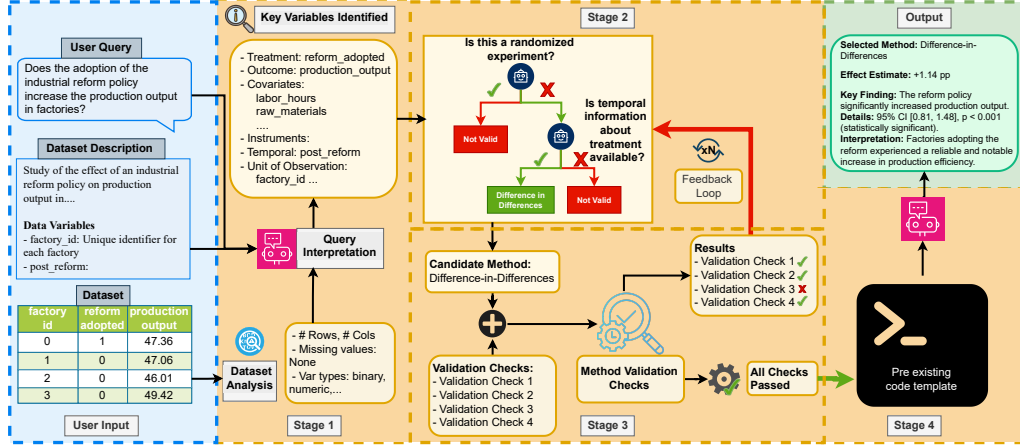

Figure 1: **CAIS workflow.** The user provides an input dataset (CSV file), its description, and an associated causal query. Guided by a decision tree and a backbone LLM, CAIS selects an appropriate estimation method, executes the code, and returns the estimated causal effect along with a natural-language interpretation.

However, existing approaches face three main limitations: (i) fine-tuned models are often narrow in scope, supporting only a limited set of causal effect measures and excluding widely used methods in applied research; (ii) general-purpose tools are primarily evaluated on causal discovery tasks, leaving their causal estimation capabilities untested; and (iii) those that are tested for causal effect estimation are evaluated on examples where users specifically mention the causal effect to be computed, which assumes prior knowledge of causal inference. These limitations are insufficient for enabling the automation of causal inference that is both comprehensive and accessible to others.

To address these limitations, we present Causal AI Scientist (CAIS), an end-to-end LLM-augmented causal tool for generating causality-driven answers to natural language queries. Given a dataset, its description, and a query, CAIS frames the task as a causal inference problem, automatically selects an appropriate method, estimates the causal effect, and interprets the result in context, as outlined in Figure 1. To select the right method, CAIS uses a structured decision tree that breaks down the selection process into focused steps. At each node, it prompts LLMs to evaluate specific features of the dataset or query, such as identifying the treatment, outcome, or instrument. This step-by-step approach reduces errors that commonly arise when relying entirely on LLMs for model selection. Additionally, CAIS performs diagnostic checks and incorporates a feedback loop to self-correct potential errors before producing a final answer.

We evaluate CAIS on CauSciBench [Acharya et al., 2025], a real-world benchmark designed to evaluate the ability of LLMs to perform causal analysis on tabular datasets. CauSciBench consists of causal queries curated from real-world empirical studies, textbook-based examples from QRData (a standard benchmark dataset for causal inference developed by Liu et al. [2024a]), and simulated scenarios. Experiments on its three subsets, real-world studies, textbook examples, and synthetic datasets, show that CAIS outperforms other baselines in selecting the appropriate causal inference method and estimating accurate causal effect values.

In summary, our contributions are:

- We propose Causal AI Scientist (CAIS), the first fully autonomous tool designed specifically for causal inference.
- We introduce a structured, rule-based decision tree that guides the method selection process.
- We perform rigorous evaluations across multiple datasets, and conduct ablation studies to demonstrate the effectiveness of CAIS.

64 2 Related Work

65 **LLMs and Causal Inference** LLMs have been applied to causal inference with text data [Dhawan
66 et al., 2024, Lin et al., 2023, Imai and Nakamura, 2024, Veljanovski and Wood-Doughty, 2024].
67 Recent research has also explored their use for causal effect estimation in tabular datasets [Liu et al.,
68 2024b, Chen et al., 2025]. However, these approaches often require users to specify the estimation
69 method or variables. Jiang et al. [2024b] introduced a fine-tuned model for causal discovery and effect
70 estimation, but it does not support methods like Instrumental Variables and Difference-in-Differences.
71 Causal-Copilot [Wang et al., 2025] expands the range of methods but was primarily evaluated on
72 causal discovery, not causal inference. Another approach builds causal graphs with LLMs [Kiciman
73 et al., 2024, Han et al., 2024], but this is limited to graph-based estimation techniques. In contrast,
74 our model automates variable and method selection using a decision tree and adds self-correction,
75 creating a fully automatic causal inference pipeline for tabular datasets.

76 **LLM-powered data analysis** Several works have studied the code generation capabilities of
77 LLMs for data science tasks, including machine learning, statistical analysis, data manipulation, and
78 visualization [Huang et al., 2022, Lai et al., 2023, Cheng et al., 2023, Nejjar et al., 2024, Jansen
79 et al., 2023]. However, these approaches require users to provide specific instructions. Wu et al.
80 [2024] extend this line of work by enabling LLM-powered tools to perform statistical reasoning and
81 generate solutions to natural language questions. However, these do not involve causal methods.
82 A promising direction for end-to-end analysis is the development of LLM-powered agents. Most
83 of these tools are geared toward machine learning tasks [Zhang et al., 2023, 2024, Huang et al.,
84 2024] or data science tasks involving both machine learning and statistical methods [Guo et al., 2024,
85 Hong et al., 2024]. The capabilities of these tools have been enhanced through case-based reasoning
86 [Guo et al., 2024], hierarchical decomposition [Hong et al., 2024], and interactive tools [Wu et al.,
87 2023]. However, these agents do not focus on causality-based analysis, which requires different
88 methodological considerations.

89 3 Problem Formulation

90 We are tasked with developing a system that can automatically perform causal effect estimation. The
91 system receives three inputs:

- 92 • A tabular dataset, $\mathcal{D}$, containing observations for multiple units.
- 93 • Metadata describing the variables and the data collection process.
- 94 • A natural-language query, q , posing a causal question about the relationships within the data.

95 The objective is to interpret the query q in the context of the dataset $\mathcal{D}$ and its metadata to produce an
96 estimate of the causal effect of interest.

97 3.1 Causal Model and Estimand

98 To formalize this task, we adopt the potential outcomes framework [Rubin, 2005]. The system must
99 first parse the query q and the metadata to identify the key variables: the **treatment** (T), the **outcome**
100 (Y), and a set of covariates (X). Each unit i has two potential outcomes: $Y_i(1)$, the outcome if the
101 unit received the treatment, and $Y_i(0)$, the outcome if it did not. Similarly, T_i denotes whether unit i
102 belongs to the treatment ($T_i = 1$) or the control ($T_i = 0$) group.

One of the causal estimands of interest is the Average Treatment Effect (ATE), defined as the expected
difference between these potential outcomes across the population:

$$\tau_{ATE} = \mathbb{E}[Y(1) - Y(0)]$$

103 However, the fundamental problem of causal inference is that for any given unit, we can only observe
104 one of its potential outcomes [Holland, 1986]. The observed outcome is $Y_i = Y_i(T_i)$. This means the
105 ATE cannot be calculated directly.

106 **Example: Job Training Program** To make this concrete, consider a dataset from a job-training
107 program (e.g., the Lalonde dataset [LaLonde, 1986]) and the query, “Does the training program
108 boost earnings?”. Here, the treatment T is program participation, the outcome Y is earnings, and

covariates X could include education, age, and prior income. The ATE would represent the average boost in earnings if everyone in the population participated in the program versus if no one did.

3.2 Identification: From Randomized to Observational Data

The process of connecting the unobservable ATE to our observed data is called **identification**. This requires making assumptions.

The simplest case is a Randomized Controlled Trial (RCT), where individuals are randomly assigned to treatment ($T = 1$) or control ($T = 0$). This randomization ensures that, on average, the two groups are identical before treatment. This satisfies the **ignorability** assumption ($(Y(1), Y(0)) \perp\!\!\!\perp T$), meaning the treatment assignment is independent of the potential outcomes. In an RCT, the ATE can be simply estimated by the difference in the average outcomes of the two groups:

$$\hat{\tau}_{ATE} = \frac{1}{N_1} \sum_{i:T_i=1} Y_i - \frac{1}{N_0} \sum_{i:T_i=0} Y_i. \quad (1)$$

However, most data is **observational**, not from an RCT. In observational data, ignorability is often violated. For instance, more motivated individuals (who might have higher earnings potential anyway) may be more likely to sign up for a job training program. This motivation is a **confounder**, a variable that affects both treatment assignment and the outcome.

To handle confounders, we rely on a stronger, untestable assumption: **conditional ignorability**. This states that the treatment assignment is independent of the potential outcomes when conditioned on all the common causes (X) of T and Y . Mathematically, it can be formulated as follows:

$$(Y(1), Y(0)) \perp\!\!\!\perp T \mid X \quad (2)$$

Along with the **Stable Unit Treatment Value Assumption (SUTVA)** (no interference between units and consistency of treatment), conditional ignorability allows us to identify the ATE by adjusting for the covariates X :

$$\tau_{ATE} = \mathbb{E}_X[\mathbb{E}[Y \mid T = 1, X] - \mathbb{E}[Y \mid T = 0, X]]$$

Estimation via Statistical Models To compute the quantity above, we use structural causal models [Pearl, 2009] to describe the relationships between Y , T , and X . A common approach is a linear structural model, which can be expressed as below:

$$Y = \alpha + X^T \beta + \tau T + \epsilon, \quad (3)$$

where α is the intercept, β is a vector of coefficients for the covariates X , τ is the treatment effect parameter, and ϵ is the unobserved error term. In this model, the coefficient τ directly corresponds to the ATE, as it represents the change in Y for a one-unit change in T after adjusting for X . We can then use an estimation method, such as linear regression, to find a sample-based estimate, $\hat{\tau}$, from the data.

3.3 The Role of the LLMs: Supplying Domain Expertise

The entire causal inference process hinges on the validity of the conditional ignorability assumption, which cannot be verified from data alone. Justifying this assumption requires **domain knowledge** to argue that the set of measured covariates X is sufficient to account for all major confounders. This is precisely where the LLMs come in. The LLMs are designed to act as a proxy for a human domain expert. By leveraging their vast knowledge base, the LLMs can analyze the dataset’s metadata and the user’s query to:

- Propose a plausible causal relationship between the variables.
- Identify the most likely confounders that must be included in the set X .
- Justify the conditional ignorability assumption, thereby enabling a principled estimation of the causal effect.

4 Methodology: CAIS

CAIS consists of four successive methodological stages, each consisting of one or more micro-tools. Every stage combines logic from established causal inference principles with LLM reasoning, which is selectively applied to sub-tasks that require human-like judgment. The overall framework is depicted in Figure 1. Detailed descriptions of the specific micro-tools used in each stage are provided in Appendix D.

Outline Specifically, our method consists of the following stages:

- **Stage 1 (Data Preprocessing & Query Decomposition)** The process begins by analyzing the dataset to identify key components, such as control and target variables (Section 4.1).
- **Stage 2 (Method Selection)** A rule-based decision tree is used to select a valid method for causal effect estimation based on the identified components (Section 4.2).
- **Stage 3 (Validation)** The standard assumptions for the selected method are then validated. If any assumption check fails, the system backtracks to Stage 2 to find an alternative method, creating a validation loop (Section 4.3).
- **Stage 4 (Method Execution & Interpretation)** Finally, once all checks pass, the chosen method is executed using predefined templates, and the final result is returned with an interpretation (Section 4.4).

4.1 Stage 1: Dataset Preprocessing & Query Decomposition

In this stage, the CAIS uses an LLM to analyze the dataset and formalize the user’s causal question. Guided by a structured prompt (see Appendix E.1 for details), in this stage we perform two sequential tasks. First, we profile the data by generating a summary of column types, missing values, and statistical distributions. Using this summary as context, we use an LLM to decompose the user’s query. It interprets the natural language request to identify and categorize the essential columns for the analysis. This involves designating the treatment, outcome, and confounder variables, as well as scanning for specialized variables—such as instrumental, running, or time-series variables—that enable specific causal methods. The final output is a structured definition of the causal problem, which serves as the input for Stage 2.

4.2 Stage 2: Method Selection

In this stage, CAIS selects a suitable causal inference method using the structured specification produced in Stage 1. The selection is performed through a rule-based decision tree that encodes standard design logic from the causal inference literature. At each branch, the system evaluates a specific property of the problem, such as whether treatment is randomly assigned, whether time and unit identifiers are present, or whether an instrumental or running variable is available. This information is already extracted in Stage 1 with deterministic rules and LLM assistance wherever necessary, ensuring transparency and reproducibility. The tree then routes the problem to one of a small number of valid methods, such as difference-in-means, ordinary least squares, difference-in-differences, etc.

By breaking the selection process into explicit and verifiable steps, the decision tree ensures both accuracy and interpretability, avoiding the opacity of direct method selection by an LLM. The resulting method choice, along with its assumptions, is then passed to Stage 3 for validation. We provide a detailed explanation of the decision tree for method selection in Appendix C.

4.3 Stage 3: Validation

This stage serves as a crucial validation and feedback mechanism, acting as a safeguard against errors from the initial analysis and method selection. CAIS performs the standard **statistical assumption checks** required for the selected method, such as the parallel trends test for Difference-in-Differences or computing the F-statistic for an Instrumental Variable (IV) analysis. If failure occurs for any of these assumptions, the system initiates a feedback loop back to Stage 2. Information from the failed validation attempt is incorporated into the context, allowing us to skip past the previously selected

node from the decision tree and move on to the next plausible candidate. We provide a detailed qualitative example of the validation loop in Appendix F.

4.4 Stage 4: Method Execution & Interpretation

Once a method successfully passes all validation checks in Stage 3, CAIS proceeds to **execution**. This stage utilizes predefined code templates with placeholders for the key variables (e.g., treatment, outcome) identified in Stage 1. This template-based strategy was chosen over LLM-powered code generation to maximize reliability and efficiency. While generating code from scratch can be flexible, it increases the risk of implementation errors and can be slow and costly due to the need for iterative debugging [Chen et al., 2025]. Our approach minimizes these risks, as its core logic is pre-verified. After the method is executed, the final step is **interpretation**. The LLM is prompted to synthesize the numerical output—such as the causal estimate and its statistical significance—into a natural language explanation that directly addresses the user’s original query. Crucially, this interpretation is presented alongside important caveats, including the results of the validation checks from Stage 3 and a clear statement of the assumptions and limitations of the chosen method. This ensures the user understands the full context and reliability of the final estimate.

5 Experimental Setup

Dataset To evaluate CAIS, we use CauSciBench [Acharya et al., 2025], a comprehensive benchmark for assessing LLMs on causal-estimation tasks. CauSciBench consists of 113 causal queries drawn from three sources: (1) QRData [Liu et al., 2024b], a benchmark dataset primarily based on causal inference textbooks; (2) published papers across multiple disciplines; and (3) synthetic datasets with known ground-truth causal effects. This collection covers a wide range of evaluation scenarios and methods used in practice. Summary statistics of CauSciBench are presented in Table 1.

Baselines Given the lack of LLM-based tools for fully automated causal inference, we compare our method against three strong prompting strategies that represent the state of the art in LLM-assisted data analysis. ReAct prompting [Yao et al., 2023] guides the model through iterative thought–action–observation cycles, which prior work shows to be highly effective for causal inference [Liu et al., 2024b]. Program of Thoughts (PoT) prompting [Chen et al., 2022] instead asks the model to produce a single, complete program that handles the entire analysis from data loading to reporting results. Finally, a Veridical Data Science–inspired prompt [Yu, 2020] emphasizes stability by requiring the model to reflect on and critique its own methodological choices before finalizing outputs. Examples of these prompts are provided in Appendix G.

Implementation Details For estimating causal effects, we use the DoWhy [Sharma and Kiciman, 2020, Blöbaum et al., 2024] and statsmodels [Seabold and Perktold, 2010] Python libraries. Our experiments use several LLMs as the reasoning backbone, including GPT-4o, Llama-3.3-70B-Instruct, and Gemini 2.5 Pro. All models were accessed via their respective APIs. To ensure reproducibility for all experiments, we used greedy decoding by setting the temperature parameter to 0.

Evaluation Metrics We evaluate our pipeline using the following metrics.

- **Method Selection Accuracy (MSA)**: Percentage of queries where the selected method $\hat{m}_i$ matches the reference method (m_i).

$$\text{MSA} = \frac{1}{N} \sum_{i=1}^N \mathbf{1}[\hat{m}_i = m_i] \times 100. \quad (4)$$

• **Mean Relative Error (MRE):** Average relative error between predicted causal effects ($\hat{\tau}_i$) and reference values (τ_i).

$$\text{MRE} = \frac{1}{N} \sum_{i=1}^N \min \left(\frac{|\hat{\tau}_i - \tau_i|}{|\tau_i|}, 1 \right) \times 100\% \quad (5)$$

To reduce sensitivity to outliers, relative error is capped at 100% per query.

In the above formulas, N denotes the total number of queries in the evaluation set.

6 Results

We evaluate the performance of CAIS against the baseline prompting strategies (Section 5). We then analyze the effectiveness of its key components, the decision tree and the validation feedback loop, through ablation studies (Section 6.1). We also provide a detailed comparative performance analysis in Appendix A and detailed error analysis B. Table 2 presents the main results, comparing CAIS with the baselines on three subsets of CauSciBench.

Table 2: Performance of CAIS and baseline prompting strategies across all datasets and LLMs. Results are reported for both **Method Selection Accuracy (MSA, higher is better)** and **Mean Relative Error (MRE, lower is better)**. Dataset blocks correspond to Textbook, Synthetic, and Real-world settings. Bold entries indicate the best value in each row. CAIS consistently outperforms baselines on MSA while maintaining competitive MRE.

CAIS shows superior method selection capabilities. Across all three datasets and models, we observe that CAIS outperforms the baselines in MSA, with significant margins in nearly all cases. For example, on the textbook dataset, o3-mini achieves an MSA of 94.1%, which is 32.6 percentage points higher than the second-best baseline. On average, CAIS improves MSA over the best-performing baseline per LLM by +22.18 points on the textbook data, +15.58 points on the synthetic data, and +14.10 points on the real data. These results demonstrate the effectiveness of our decision-tree-based method selection and validation feedback loop compared to relying solely on LLM reasoning.

CAIS achieves competitive causal estimation accuracy. Performance trends in MRE are more nuanced. On the synthetic and real datasets, our model performs competitively, achieving either the lowest or second-lowest MRE for most LLMs. However, a notable exception is the Textbook dataset, where our model consistently underperforms.

We attribute this discrepancy to a key design choice intended to prevent incorrect implementation. Our model uses pre-verified code templates and does not retry execution if an error occurs, which can result in a substantial MRE penalty on failure. In contrast, the baseline methods use iterative retries to ensure they always return a numerical estimate, even if the chosen causal method is fundamentally inappropriate for the data.

(a) Decision tree vs. LLM-based method selection. (b) Impact of the validation feedback loop.

Table 3: Ablation results: (a) decision tree vs. LLM-based method selection, and (b) validation feedback loop.

6.1 Ablation Studies

We conduct two ablation studies to assess the role of the core components in our pipeline: the *decision tree* and the *validation loop*. For the decision tree ablation, we compare CAIS with a variant that removes the decision tree and prompts an LLM to directly select the method. For the validation loop ablation, we compare CAIS with a variant without the validation loop, which simply uses the initially selected method without further checks.

Decision tree significantly improves method-selection accuracy. The results in Table 3a clearly show that incorporating a structured decision tree for method selection leads to substantially higher MSA compared to relying solely on the LLM’s direct judgment. The decision tree decomposes the selection process into a sequence of targeted diagnostic questions, each focused on a specific dataset property (e.g., treatment timing, presence of instruments, covariate balance). This step-by-step approach constrains the LLM’s reasoning to smaller, well-defined decisions, reducing the likelihood of overgeneralization or bias toward familiar methods. For example, on QRData, GPT-4o improves from 48.4% to 74.4% and o3-mini from 50% to 94.1%. Overall, the decision-tree-based approach is superior in performance compared to solely relying on LLMs.

The validation loop helps reduce the performance gap between weaker LLMs and stronger LLMs. As shown in Table 3b, the validation feedback loop is a critical component, especially for correcting errors from less capable models. This effect is most evident with GPT-4o-mini, whose accuracy improves dramatically from 41.2% to 74.3% (+33.1 points) on QRData and from 33.3% to 65.2% (+31.9 points) on the Real dataset. The loop provides this significant boost by allowing weaker models to recover from incorrect initial method selections, to which they are more prone.

Conversely, the benefits are less pronounced for stronger models like GPT-4o. Since these models are more likely to select the correct method on the first attempt, the validation loop offers only marginal gains and can occasionally lead to a slight decrease in performance.

7 Conclusion

In this work, we introduce Causal AI Scientist (CAIS), an end-to-end tool that maps natural language queries and datasets to formal causal inference tasks by automatically selecting appropriate methods and interpreting results. When evaluated across diverse causal inference tasks using three datasets, CAIS consistently outperforms baseline prompting strategies in method selection and achieves competitive performance in causal effect estimation, particularly on structured datasets such as QRData and synthetic examples. These results highlight the value of CAIS’s decision-tree-based approach, which decomposes complex reasoning into interpretable steps. This not only improves estimation accuracy but also enhances robustness and transparency—qualities critical for researchers and practitioners in social science, healthcare, and related fields. Moreover, CAIS’s strong performance on well-structured datasets suggests that real-world outcomes can be further improved with better data preprocessing, reinforcing its utility as a trustworthy tool for non-experts seeking accessible and interpretable causal analysis.

Metric	Baseline	CAIS	Change (%)
<i>General Statistics</i>			
Total Queries	1551	585	–
Successful Queries	1476	512	–
Total Retries	930	159	–
Retries per Query (%)	59.96	27.18	↓ 54.69
Method Match Rate (%)	52.08	76.20	↑ 46.3
Mean Error (%)	35.38	37.66	↑ 6.4
<i>Error Breakdown (%)</i>			
Execution & Runtime Error	34.39	22.91	↓ 33.4
Method Mismatch	29.77	21.20	↓ 28.8
Data Loading Failure	3.10	0.00	↓ 100.0
Missing Result	0.76	6.84	↑ 800.0

Table 4: Comparison of performance and error types between baseline and CAIS. Arrow indicates direction of change from baseline to CAIS.

Figure 2: Confusion matrix showing method selection performance of CAIS (GPT-4o).

A Comparative Performance Analysis

Here, we compare the overall performance of CAIS, which uses a structured approach, with baselines that rely on prompting-based LLM code generation, focusing on execution stability, error types, and the frequency of retries.

- **Higher Method Selection Accuracy:** CAIS achieves a 46.3% higher method match rate than the baseline (76.2% vs. 52.08%), indicating more accurate identification of appropriate causal methods.
- **Substantial Reduction in Retries:** CAIS reduces total retries by 54.6% per query (In CAIS, a retry refers to feedback via validation loop), suggesting more robust and executable outputs due to structured prompt generation and template-based code execution.
- **Improved Execution Stability:** Execution and runtime errors are reduced by 33.4%, and method mismatches decrease by 28.8%, reflecting enhanced reliability in model reasoning and implementation.
- **No Data Loading Failures:** CAIS handles datasets more reliably with 0% data loading failures compared to 3.1% in the baseline.
- **Trade-offs in Estimation Quality:** While CAIS increases mean error slightly (from 35.38% to 37.66%), this may stem from using more advanced methods rather than defaulting to simple linear regression.

B Error Analysis

This section provides a qualitative breakdown of the model’s primary failure modes. We analyze common error patterns to identify their root causes and determine which stages of the pipeline are most vulnerable.

- **Incorrect Variable Selection:** LLMs frequently misinterpret temporal covariates, such as birth year or quarter indicators, as observation time points. This misinterpretation can erroneously lead to the selection of Difference-in-Differences as the causal inference method. Additionally, LLMs often misidentify treatment and outcome variables, particularly when column names lack clear descriptive labels or contain ambiguous terminology.
- **Wrong Method Selection:** As demonstrated in Figure 2, LLMs misclassify Randomized Controlled Trials as Encouragement Designs, leading to the selection of Instrumental Variables instead of linear regression. Similarly, for synthetic datasets, the model fails to identify Instrumental Variables as the optimal method in three instances. This pattern underscores the inherent challenge of selecting valid instruments based solely on data descriptions.
- **Incorrect Data Formats:** Implementation errors also stem from inconsistent data formatting. Specifically, certain variables are encoded as strings when causal inference packages like DoWhy require numerical inputs, creating compatibility issues that compromise execution.

C Explanation of decision tree

C.1 Notation

We first define key notation used throughout this guide:

- **Y:** Outcome (the variable we want to understand or predict)
- **T:** Treatment assignment (whether a unit is assigned to treatment; $T = 0$ indicates the control group, $T = 1$ indicates the treatment group)
- **D:** Treatment uptake (actual receipt of treatment, used in encouragement designs where assignment is not the same as uptake)
- **Z:** Instrumental variable (a variable used to identify causal effects in the presence of unobserved confounding)
- **M:** Mediator (a variable that lies on the causal pathway between treatment and outcome)
- **U:** Unobserved confounder (a variable that affects both treatment and outcome but is not measured)
- **X:** Covariates (observed variables that may influence treatment or outcome)
- **i:** Individual units of analysis (for example people, organizations, or countries)

C.2 Randomized Controlled Trials (RCTs)

We begin by determining if the data comes from a Randomized Controlled Trial (RCT). RCTs are the gold standard for causal inference because random assignment eliminates confounding by making treatment and control groups comparable on average.

C.2.1 Encouragement Designs

Within RCTs, we first check if the data comes from an encouragement design. An encouragement design refers to scenarios where treatment assignment is random, but not all assignees accept or take up their assigned treatment, i.e., $T_i \neq D_i$ [Holland, 1988].

A classic example is the deworming experiment by Miguel and Kremer [Miguel and Kremer, 2004]. Students were randomly assigned to receive deworming drugs, but not all students who were assigned actually took the drugs. In such cases, the corresponding relation would be:

T (randomly assigned to get dewormed) $\rightarrow D$ (actually took the drug) $\rightarrow Y$ (school enrollment).

569 To estimate the effect of actual treatment uptake (rather than just assignment), one uses instrumental
570 variable analysis, with the random assignment T serving as an instrument for actual uptake D .

571 C.2.2 Standard RCT Analysis

572 If the data is not from an encouragement design, meaning everyone accepts their assigned treatment,
573 this is the classic RCT analysis. One can simply compute the difference in means between the
574 treatment and control groups.

575 In many cases, the dataset might have pretreatment variables (baseline characteristics measured
576 before treatment). While one can still compute a simple difference in means, the trend in the literature
577 is to include these pretreatment variables as controls in an Ordinary Least Squares regression model.
578 This is primarily done to improve the precision of the estimates (reduce the standard errors) rather
579 than to address bias, since randomization already handles confounding.

580 C.3 Observational Studies

581 If the data is not from an RCT, we move to observational methods. Here, we cannot rely on
582 randomization to eliminate confounding. Techniques to address confounding varies according to the
583 characteristics of the data.

584 C.3.1 Binary Treatments with Temporal Variation

585 **Difference in Differences (DiD)** For binary treatments, we first consider Difference in Differences
586 when time based confounding is a concern. DiD requires information about treatment timing, which
587 could be either binary (pre or post treatment) or staggered (different units adopting treatment at
588 different time periods).

589 A classic example is the minimum wage study by Card and Krueger [Card and Krueger, 1994].
590 Pennsylvania and New Jersey are two states with similar characteristics. New Jersey increased the
591 minimum wage, but Pennsylvania did not. We want to know the effect of the minimum wage policy
592 on employment. However, over time many things change that could affect employment outcomes.
593 DiD uses the control group (Pennsylvania) as a counterfactual. Since the two states are similar, they
594 would have evolved similarly absent treatment. By subtracting the changes in the control state from
595 the changes in the treated state, DiD removes time varying confounders that affect both states equally.
596 If no temporal information is available, DiD cannot be used.

597 **Regression Discontinuity Design (RDD)** If DiD is not applicable, we check for Regression
598 Discontinuity Design. RDD exploits situations where treatment assignment is determined by a
599 threshold or cutoff rule, creating a sharp change in treatment status at a specific value of a running
600 variable.

601 For example, to study the impact of alcohol consumption on road accidents [Carpenter and Dobkin,
602 2009], we can use the fact that alcohol consumption is legally allowed after age 21 in the United
603 States. By comparing accident rates for people just above and below age 21, we can identify the causal
604 effect of legal drinking. Here, age is the running variable, and treatment assignment is: treatment = 1
605 if age ≥ 21 , treatment = 0 if age < 21 . If there is no clear running variable with a threshold that
606 determines treatment assignment, RDD cannot be used.

607 C.3.2 General Methods for Binary Treatments

608 DiD and RDD can potentially work when the dataset meets certain characteristics. This would be
609 the presence of treatment and outcome information over time for DiD and the presence of a running
610 variable for RDD. If the dataset does not meet the respective criteria, we can rule those methods out.
611 Next, we describe a more general group of methods.

612 **Backdoor adjustment** Observational studies often rely on the conditional ignorability assumption:
613 treatment assignment is independent of potential outcomes conditional on all observed confounders.
614 This requires that all relevant confounders are observed. We can satisfy this assumption using Pearl's
615 backdoor adjustment criterion [Pearl, 2000]. For causal effect estimation, we use inverse probability
616 weighting (IPW) using propensity scores [Rosenbaum and Rubin, 1983] and matching [Stuart, 2010].

617 Propensity score measures the probability that a unit receives the treatment given the observed
618 covariates. Mathematically, $e(X) = P(T = 1|X)$. One can estimate propensity scores by fitting a
619 logit or a probit model with X as the dependent variable and T as the independent variable. To choose
620 between IPW and matching, we assess covariate balance using the standardized mean difference
621 (SMD) [Greifer, 2025]:

$$\text{SMD} = \frac{\bar{X}_{\text{treated}} - \bar{X}_{\text{control}}}{\sqrt{\frac{s_{\text{treated}}^2 + s_{\text{control}}^2}{2}}}.$$

622 where $\bar{X}_{\text{treated}}$ denotes the mean of the covariates in the treated group, and s_{treated}^2 their variance.
623 Analogously, $\bar{X}_{\text{control}}$ and s_{control}^2 refer to the mean and variance of the covariates in the control group.
624 If covariates are well balanced (typically $\text{SMD} < 0.1$), we use IPW methods directly. If covariates
625 are poorly balanced, we use matching techniques to improve balance before estimating causal effects.

626 C.3.3 Methods for Unmeasured Confounding

627 Backdoor adjustment based methods fail if important confounders are unobserved. The presence
628 of unobserved confounders decision is mostly made by combining domain knowledge and the data
629 generating process. In cases where unobserved confounders are suspected, we can use Instrumental
630 Variable or frontdoor estimation.

631 **Instrumental Variables (IV)** The first approach is IV analysis [Imbens, 2014], which requires a
632 valid instrument satisfying two conditions:

- 633 1. **Relevance:** The instrument must be correlated with treatment ($\text{Cov}(Z, T) \neq 0$).
- 634 2. **Exclusion restriction:** The instrument should affect the outcome only through treatment,
635 not directly.

636 The relevance assumption is testable, while the exclusion restriction must be justified through domain
637 knowledge. A classic example of IV analysis is Card's study [Card, 1993] estimating returns to years
638 of education, using geographic proximity to college as an instrument. Many unobserved factors
639 (parental income, personal motivation) affect earnings and education, making it difficult to isolate
640 education's causal effect. However, proximity to college affects educational attainment (relevance)
641 but has no direct effect on earnings except through education (exclusion restriction). Finding good
642 instruments is challenging, and quite often the dataset does not contain good candidates for an
643 instrument.

644 **Frontdoor Criterion** Another option that may work in the presence of unobserved confounders is
645 frontdoor estimation based on the frontdoor criterion [Pearl, 2000]. This works when there exists a
646 mediator that completely captures the treatment's effect on the outcome and satisfies the frontdoor
647 criterion:

- 648 • The mediator must completely intercept the path from the treatment to the outcome.
- 649 • The relationship between the treatment and the mediator must not be confounded.
- 650 • The treatment must block all confounding paths between the mediator and the outcome.

651 C.3.4 Method Hierarchy

652 When multiple methods are applicable, there is a clear preference hierarchy:

Instrumental Variables > Frontdoor Criterion > Backdoor Adjustment.

653 This hierarchy exists because IV and frontdoor methods can handle unobserved confounders, while
654 backdoor adjustment requires that all confounders are observed. However, IV and frontdoor methods
655 are less generally applicable, since finding valid instruments or suitable mediating variables is
656 often challenging. Backdoor adjustment methods are more widely applicable but require stronger
657 assumptions about confounding.

658 C.3.5 Nonbinary treatments

659 For nonbinary treatments in observational studies, we consider three methods: instrumental variables
 660 (IV), frontdoor adjustment, and generalized propensity scores using the backdoor adjustment set.
 661 IV and frontdoor approaches apply almost exactly as in the case of binary treatments described
 662 above. Backdoor estimation also works similarly, except that we use a different estimation method to
 663 compute causal effects. In this case, we use generalized propensity scores, which extend the idea
 664 of propensity scores to continuous treatments [Hirano and Imbens, 2004]. The scores are computed
 665 using the backdoor adjustment set.

Figure 3: Decision-tree that guides method selection in CAIS. We prompt an LLM to generate responses to queries corresponding to the decision nodes, and traverse the tree accordingly before reaching a leaf node, which corresponds to a method.

666 D Detailed Methodology

667 In this section we extend the Methodology of CAIS discussed in Section 4 in detail. CAIS operates
668 in four sequential stages. Each stage comprises one or more micro-tools that pass a typed artifact
669 to the next stage. A validation loop connects Stage 3 back to Stage 2 when assumptions fail. In
670 total, CAIS uses eight micro-tools: (1) `input_parser`, (2) `dataset_analyzer`, (3) `query_interpreter`, (4)
671 `method_selector`, (5) `method_validator`, (6) `method_executor`, (7) `explanation_generator`, and (8)
672 `output_formatter`. All tools read/write a shared typed state (dataset profile, normalized query, analysis
673 plan, selected method with assumptions, diagnostics, estimates, and final report).

674 D.1 Stage 1: Data Preprocessing & Query Decomposition

675 We begin by using `input_parser` tool to analyze user-specified causal queries and extract three
676 key components: the *query type*, the *relevant variables*, and any *explicit constraints*. It adopts a
677 hybrid strategy combining regex-based heuristics with LLM-driven structured parsing. A tailored
678 prompt E.1, enriched with dataset context when available, guides the LLM to classify the query
679 (e.g., `EFFECT_ESTIMATION`, `COUNTERFACTUAL`, `CORRELATION`, `DESCRIPTIVE`, or `OTHER`) and to output
680 a structured JSON conforming to a predefined schema. This schema enforces explicit roles for
681 variables (treatment, outcome, covariates, grouping variables, instruments) and records constraints or
682 dataset paths if mentioned. The LLM output is validated to ensure logical consistency (e.g., requiring
683 both treatment and outcome for effect estimation queries) and alignment with dataset columns when
684 available. Regex-based matching serves as a complementary mechanism, particularly for dataset path
685 extraction, thereby improving robustness. The final output is a standardized dictionary encapsulating
686 the original query, its type, extracted variables, constraints, and dataset path.

687 Following this, the `dataset_analyzer` tool profiles the dataset to identify characteristics relevant
688 for causal inference. It begins by extracting basic metadata such as the number of rows, columns,
689 file name, and data types. A detailed analysis is then conducted to detect *temporal structures*,
690 *panel data patterns*, and *potential discontinuities*, alongside computing correlations among numeric
691 variables. The module further identifies *potential treatments* and *outcomes*, either heuristically or
692 with LLM assistance, and assesses candidate *instrumental variables*. The prompts used in this stage
693 are relatively light weight and mainly framed as direct questions to the LLM, an example prompt
694 for identifying potential treatment and outcome variables can be found in Appendix E.2. For binary
695 treatment candidates, it computes per-group summary statistics (e.g., group sizes, means, and standard
696 deviations of covariates) to facilitate balance checks. Additionally, it records missing values, unique
697 value counts, and column categorizations to provide a structured overview of the dataset. The final
698 output is a comprehensive dictionary that consolidates dataset information, candidate causal variables,
699 detected structures, and diagnostic statistics.

700 Finally, the `query_interpreter` reconciles the normalized query with the dataset profile to materi-
701 alize the treatment variable T , outcome Y , admissible covariates X , and any design-specific fields
702 (instruments Z , running variable R with cutoff c , time and group indicators for DiD, etc.). For each of
703 these fields, the system issues targeted prompts to an LLM, these structured prompts can be found in
704 Appendix E.3. The responses are aggregated and validated to ensure coherence with both the dataset
705 schema and causal design assumptions. The final output is a structured *analysis plan* comprising
706 named columns, encoding details (e.g., reference levels, interaction terms), and a canonical estimand
707 (such as ATE, ATT, LATE, sharp/fuzzy RDD, or DiD horizon), which then serves as the input for
708 subsequent method selection phase.

709 D.2 Stage 2: Method Selection

710 Given the analysis plan, the `method_selector` chooses a candidate estimator via a deterministic
711 decision tree that encodes standard causal design logic. The selector also emits an assumption
712 checklist and an ordered fallback list to support backtracking. This stage is completely deterministic
713 and requires no involvement of LLMs. The design choice behind the nodes of the decision tree is
714 already discussed in great detail in Appendix C.

715 D.3 Stage 3: Validation

716 Once a candidate estimator is selected, the **method_validator** module verifies whether the assumptions required for its validity hold in the given dataset. This includes statistical diagnostics (e.g.,
717 overlap and positivity checks for treatment assignment, relevance and exogeneity tests for instruments,
718 bandwidth support for RDD, and parallel trends diagnostics for DiD). The validator also cross-checks
719 variable roles (treatment, outcome, covariates, instruments, etc.) against the dataset schema to ensure
720 consistency. Failures in any diagnostic trigger a backtracking mechanism: the system reverts to
721 the Method Selector's fallback list to propose an alternative estimator whose assumptions are more
722 compatible with the data. This creates a validation loop that guarantees every executed method
723 is grounded in both causal theory and empirical feasibility, while preserving determinism in the
724 diagnostic procedures. In this stage as well no LLMs are involved.
725

726 D.4 Stage 4: Method Execution & Interpretation

727 On a validated design, the Method Executor runs a pre-verified estimator template (statsmodels/2SLS,
728 DiD with appropriate fixed effects, local polynomial RDD, matching/weighting for PSM/PSW,
729 GPS, diff-in-means). Execution favors templates over code-generation for stability and speed. One
730 cross-cutting prompt, `STATSMODELS_PARAMS_IDENTIFICATION_PROMPT_TEMPLATE`,
731 helps select the correct coefficient(s) to report when formulas include encodings or interactions
732 (used by linear/GLM-style estimators). Several methods expose small, function-local LLM assists
733 for parameter suggestions or narrative—e.g., IV, RDD, DiD, GPS/backdoor/diff-in-means/linear
734 regression helpers, each constrained to strict JSON and backed by deterministic fallbacks. Finally
735 Explanation Generator then converts structured artifacts (chosen design, diagnostics, estimates) into
736 a concise, dataset-specific justification and interpretation, while the Output Formatter assembles the
737 final response object with numeric results, uncertainty, method card (assumptions & checks), and a
738 short plain-language answer for downstream rendering.

739 E Methodology Prompts

740 E.1 Causal Query Parsing Prompt

Analyze the following causal query **strictly in the context of the provided dataset information (if available)**. Identify the query type, key variables (mapping query terms to actual column names when possible), constraints, and any explicitly mentioned dataset path.

User Query: "{query}"

{dataset_context}

Guidance for Identifying Query Type:

- **EFFECT_ESTIMATION**: Look for keywords like "effect", "impact", "influence", "cause", "affect", "consequence". Also consider questions asking "how does X affect Y?" or comparing outcomes between groups based on an intervention.
- **COUNTERFACTUAL**: Look for hypothetical scenarios, often using phrases like "what if", "if X had been", "would Y have changed", "imagine if", "counterfactual".
- **CORRELATION**: Look for keywords like "correlation", "association", "relationship", "linked to", "related to". These queries ask about statistical relationships without necessarily implying causality.
- **DESCRIPTIVE**: Queries that ask for summaries, descriptions, trends, or statistics about the data without investigating causal links (e.g., "Show sales over time", "What is the average age?").
- **OTHER**: Use if the query does not fit any of the above categories.

Choose the most appropriate type from: `EFFECT_ESTIMATION`, `COUNTERFACTUAL`, `CORRELATION`, `DESCRIPTIVE`, `OTHER`.

Variable Roles to Identify:

- **treatment**: The intervention or variable whose effect is being studied.

741

- **outcome:** The result or variable being measured.
- **covariates_mentioned:** Variables explicitly mentioned to control for or adjust for.
- **grouping_vars:** Variables identifying specific subgroups for analysis (e.g., "for men", "in the sales department").
- **instruments_mentioned:** Variables explicitly mentioned as potential instruments.

Constraints: Conditions applied to the analysis (e.g., filters on columns, specific time periods).

Dataset Path Mentioned: Extract the file path or URL if explicitly stated in the query.

Output: ONLY a valid JSON object matching this schema (no explanations or surrounding text):

```
{
  "query_type": "<Identified Query Type>",
  "variables": {
    "treatment": ["<Treatment Variable(s) Mentioned>"],
    "outcome": ["<Outcome Variable(s) Mentioned>"],
    "covariates_mentioned": ["<Covariate(s) Mentioned>"],
    "grouping_vars": ["<Grouping Variable(s) Mentioned>"],
    "instruments_mentioned": ["<Instrument(s) Mentioned>"]
  },
  "constraints": ["<Constraint 1>", "<Constraint 2>"],
  "dataset_path_mentioned": "<Path Mentioned or null>"
}
```

If Dataset Context is provided, ensure variable names in the output JSON correspond to actual column names where possible. If no context is provided, or if a mentioned variable doesn't map directly, use the phrasing from the query. Respond with only the JSON object.

742

743 E.2 Light Weight Inline Prompts for Dataset Analysis

Prompt:

You are an expert causal inference data scientist. Identify potential treatment and outcome variables from this dataset.

Dataset Description: {description_text}

Dataset Columns: {columns_list}

Column Types: {column_types}

Binary Columns (good treatment candidates): {binary_cols}

Instructions:

1. Identify **TREATMENT** variables: interventions, treatments, programs, policies, or binary state changes. Look for binary variables or names with "treatment", "intervention", "program", "policy", etc.
2. Identify **OUTCOME** variables: results, effects, or responses to treatments. Look for numeric variables (especially non-binary) or names with "outcome", "result", "effect", "score", etc.

Output: ONLY a valid JSON object with two lists:

```
{
  "potential_treatments": ["treatment_a", "program_b"],
  "potential_outcomes": ["result_score", "outcome_measure"]
}
```

744

746

Instrumental Variable Identification Prompt

Prompt:

You are a causal inference assistant tasked with assessing whether a valid Instrumental Variable (IV) exists in the dataset. A valid IV must satisfy **all** of the following conditions:

1. **Relevance:** It must causally influence the Treatment.
2. **Exclusion Restriction:** It must affect the Outcome only through the Treatment — not directly or indirectly via other paths.
3. **Independence:** It must be as good as randomly assigned with respect to any unobserved confounders affecting the Outcome.
4. **Compliance (for RCTs):** If the dataset comes from a randomized controlled trial or experiment, IVs are only valid if compliance data is available i.e., if some units did not follow their assigned treatment. In this case, the random assignment may be a valid IV, and compliance is the actual treatment variable. If compliance related variable is not available, do not select IV.
5. The instrument must be one of the listed dataset columns (not the treatment itself), and must not be assumed or invented.

You should **only suggest an IV if you are confident that all the conditions are satisfied**. Otherwise, return "NULL".

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Treatment: {treatment}
- Outcome: {outcome}
- Available Columns: {column_info}

Output: Return a JSON object with the following structure:

```
{ "instrument_variable": "COLUMN_NAME_OR_NULL" }
```

747

RDD Identification Prompt

Prompt:

You are an expert causal inference assistant helping to determine if Regression Discontinuity Design (RDD) is applicable for quasi-experimental analysis.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Identified Treatment (tentative): {treatment}
- Identified Outcome (tentative): {outcome}
- Available Columns: {column_info}

Task: Your goal is to check if there is a **Running Variable**, i.e., a variable that determines treatment/control.

- If the variable is above a certain cutoff, the unit is categorized as treated; if below, it is control.
- The running variable must be numeric and continuous. Do not use categorical or low-cardinality variables.

748

- The treatment variable must be binary. If not, RDD is not valid.

Output: Respond ONLY with a valid JSON object. If RDD is not suggested by the context, return null for both fields.

```
{ "running_variable": "COLUMN_NAME_OR_NULL", "cutoff_value": NUMERIC_VALUE_OR_NULL }
```

Examples:

```
{ "running_variable": "test_score", "cutoff_value": 70 }
{ "running_variable": null, "cutoff_value": null }
```

749

RCT Identification Prompt

Prompt:

You are an expert causal inference assistant helping to determine if the data comes from a Randomized Controlled Trial (RCT). Your goal is to assess if the treatment assignment mechanism described or implied was random.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Identified Treatment (tentative): {treatment}
- Identified Outcome (tentative): {outcome}
- Available Columns: {column_info}

Output: Respond ONLY with a valid JSON object matching the required schema.

```
{ "is_rct": BOOLEAN_OR_NULL }
```

Examples:

```
{ "is_rct": true }    # RCT likely
{ "is_rct": false }   # Observational likely
{ "is_rct": null }    # Unsure
```

750

Treatment Reference Identification Prompt

Prompt:

You are a causal inference assistant.

Dataset Information:

- Dataset Description: {description}
- Identified Treatment Variable: "{treatment_variable}"
- Unique Values in Treatment Variable (sample): {treatment_variable_values}
- User Query: {query}

Task: Based on the user query, determine if it specifies a particular category of the treatment variable {treatment_variable} that should be considered the control, baseline, or reference group for comparison.

Examples:

- Query: "Effect of DrugA vs Placebo" → Reference for treatment "Drug" = "Placebo"
- Query: "Compare ActiveLearning and StandardMethod against NoIntervention" → Reference for "TeachingMethod" = "NoIntervention"

751

If a reference level is clearly specified or strongly implied **and** it is one of the unique values provided, identify it. Otherwise, state null. If multiple values seem like controls (e.g., "compare A and B vs C and D"), return null for now.

Output: Return ONLY a JSON object adhering to this schema:

```
{
  "reference_level": "string_representing_the_level_or_null",
  "reasoning": "string_or_null_brief_explanation"
}
```

752

Interaction Term Identification Prompt

Prompt:

You are a causal inference assistant.

Your task is to determine whether the user query suggests the inclusion of an interaction term between the treatment and one covariate, specifically to assess heterogeneous treatment effects (HTE).

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Identified Treatment Variable: {treatment_variable}
- Available Covariates (name: type): {covariates_list_with_types}

Instructions:

- ONLY suggest an interaction if the query explicitly mentions treatment across a subgroup.
- DO NOT suggest an interaction if the query asks for an overall average effect or does not mention subgroup analysis.
- If unsure, default to no interaction.

Output Schema:

```
{
  "interaction_needed": boolean,
  "interaction_variable": string_or_null,
  "reasoning": string
}
```

Examples:

```
{
  "interaction_needed": true,
  "interaction_variable": "gender",
  "reasoning": "Query asks if the treatment effect is for men."
}

{
  "interaction_needed": false,
  "interaction_variable": null,
  "reasoning": "Query asks for the overall average treatment effect,
               no specific subgroups mentioned for effect heterogeneity."
}
```

753

Treatment Variable Identification Prompt

Prompt:

You are an expert in causal inference. Your task is to identify the **treatment variable** in a dataset in order to perform a causal analysis that answers the user's query.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- List of Available Variables: {column_info}

Task: Based on the query, dataset description, and available variables, determine which variable is most likely to serve as the treatment variable.

If a clear treatment variable cannot be determined, return null.

Output Schema:

```
{ "treatment": "COLUMN_NAME_OR_NULL" }
```

754

Outcome Variable Identification Prompt

Prompt:

You are an expert in causal inference. Your task is to identify the **outcome variable** in a dataset in order to perform a causal analysis that answers the user's query.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Available Variables: {column_info}

Task: Based on the query, dataset description, and available variables, determine which variable is most likely to serve as the outcome variable in the causal analysis.

Do not speculate. If a clear outcome variable cannot be identified, return null.

Output Schema:

```
{ "outcome": "COLUMN_NAME_OR_NULL" }
```

755

Covariates Identification Prompt

Prompt:

You are an expert in causal inference. Your task is to identify the **pre-treatment variables** in a dataset that can be used as controls in a causal estimation model to answer the user's query.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Available Variables: {column_info}
- Treatment Variable: {treatment}
- Outcome Variable: {outcome}

Task: Pre-treatment variables are those that are measured **before** the treatment is applied and are **not affected** by the treatment. These variables can be used as controls in the causal model.

756

For example, in an RCT with outcome Y , treatment T , and pre-treatment variables $X1$, $X2$, $X3$, we can perform a regression of the form:

$$Y \sim T + X1 + X2 + X3$$

Based on the information above, return a list of variables that qualify as pre-treatment variables from the available columns. If no suitable pre-treatment variables can be identified, return an empty list.

Output Schema:

```
{ "covariates": ["LIST_OF_COLUMN_NAMES_OR_EMPTY_LIST"] }
```

757

Estimand Identification Prompt

Prompt:

You are an expert in causal inference. Your task is to determine the appropriate **estimand** to answer a given query.

Information Provided:

- User Query: {query}
- Dataset Description: {dataset_description}
- Variables in Dataset: {dataset_columns}
- Treatment Variable: {treatment}
- Outcome Variable: {outcome}

Task: Given this information, decide whether the **Average Treatment Effect (ATE)** or the **Average Treatment Effect on the Treated (ATT)** is more appropriate for answering the query.

Output: Only return the estimand name:

"att" or "ate"

758

Confounder Identification Prompt

Prompt:

You are an expert in causal inference. Your task is to identify potential **confounders** in a dataset that should be adjusted for when estimating the causal effect described in the user query.

Information Provided:

- User Query: {query}
- Dataset Description: {description}
- Available Variables: {column_info}
- Treatment Variable: {treatment}
- Outcome Variable: {outcome}

Definition of Confounder: A **confounder** is a variable that:

1. Affects the treatment (influences who receives the treatment),
2. Affects the outcome,
3. Is not caused by the treatment (must be a pre-treatment variable),
4. Is not a mediator between treatment and outcome.

759

These variables can create spurious associations between treatment and outcome if not adjusted for.

Task: Based on the user query and the dataset description, identify which variables are likely to be confounders. Only include variables that you believe causally affect both treatment and outcome. If uncertain, only include variables where the justification is clear from the query or description.

Output Schema:

```
{ "confounders": ["LIST_OF_COLUMN_NAMES_OR_EMPTY_LIST"] }
```

760

DiD Term Identification Prompt

Prompt:

You are a causal inference assistant tasked with determining whether a valid Difference-in-Differences (DiD) **interaction term** already exists in the dataset.

This DiD term should be a **binary variable** indicating whether a unit belongs to the **treatment group after treatment was applied**.

For example, if a policy was enacted in 2020 for a particular state, then the DiD term would equal 1 for units from that state in years after 2020, and 0 otherwise.

Information Provided:

- User Query: {query}
- Time Variable: {time_variable}
- Group Variable: {group_variable}
- Dataset Description: {description}
- Available Columns: {column_info}
- Column Types: {column_types}

Output: Return your answer as a valid JSON object with the following format:

```
{ "did_term": "COLUMN_NAME_OR_NULL" }
```

761

F Detailed Study: Method Validation Loop

763 This example presents the complete prompt employed in the validation feedback loop of CAIS.

Worked Example: Method Validation

Query: Does having access to electricity increase kerosene expenditures?

Dataset: electrification_data.csv

Database: All_Data Collection (Rural Electrification Survey)

Description: This household survey covers 686 households in 120 habitations across Uttar Pradesh, India. Using a geographic eligibility rule (households within 20–35 m vs. 45–60 m of a power pole), it records monthly expenditures on food, education, kerosene, total expenditure, appliance ownership, lighting usage, and satisfaction measures to assess the impact of electrification.

Method Validation: During validation, the pipeline fits local regressions on kerosene expenditure immediately below and above the 40 m cutoff to test for a sharp discontinuity. When using the lightweight gpt-4o-mini model, the agent misidentified the “distance” variable effectively widening the window around 40 m and consequently observed no statistically

764

significant jump in outcomes at the threshold ($p > 0.05$). Because a pronounced, localized shift at the cutoff is the cornerstone of RDD, this absence of any detectable discontinuity constituted a direct violation of the RDD assumptions and led to its rejection. The system then automatically backtracked down the decision tree, removed RDD from consideration, and evaluated the next class of methods. Given the observational nature of the data and the rich set of covariates, it advanced to propensity-score-matching as the alternative method to create balanced treatment and control groups before estimating the effect.

765

766 G Baselines Prompts

767 Here, we display all the prompts used for the baselines: ReAct, PoT, and Veridical Prompts for causal
768 inference.

ReAct Prompt Example

Prompt: You are working with a pandas DataFrame in Python. The name of the DataFrame is df.

You should use the tools below to answer the question posed to you:

python_repl_ast: A Python shell. Use this to execute Python commands. Input should be a valid Python command. When using this tool, sometimes output is abbreviated—make sure it does not look abbreviated before using it in your answer.

Use the following format:

- **Question:** the input question you must answer
- **Thought:** what you should do next
- **Action:** the action to take (e.g., python_repl_ast)
- **Action Input:** the input to the action (code to execute)
- **Observation:** the result of the action

(This Thought/Action/Action Input/Observation can repeat N times.)

Final Answer: The final answer to the original input question. Please provide a structured response including the following:

- Method
- Causal Effect
- Standard Deviation
- Treatment Variable
- Outcome Variable
- Covariates
- Instrument / Running Variable / Temporal Variable
- Results of Statistical Test
- Explanation for Model Choice
- Regression Equation

Instructions:

- Import libraries as needed.
- Do **not** create any plots.
- Use the `print()` function for all code outputs.
- If you output an Action step, stop after generating the Action Input and await execution.
- If you output the Final Answer, do not include an Action step.

769

Example Usage of python_repl_ast:

Action: python_repl_ast

770

Program of Thoughts based Prompt

Prompt: You are a data analyst with strong quantitative reasoning skills. Your task is to answer a data-driven causal question using the provided dataset. The dataset description and query are given below.

You should analyze the **first 10 rows** of the dataset and then write Python code to generalize the analysis to the full table. You may use any Python libraries.

The returned value of the program should be the final answer. Please follow this format:

```
def solution():
    # import libraries if needed
    # load data from {self.dataset_path}
    # write code to get the answer
    # return answer
```

```
print(solution())
```

Dataset Description: {self.dataset_description} **Dataset Path:** {self.dataset_path}

First 10 rows of data: {df.head(10)}

Question: {self.query}

Example Methods (choose one if applicable):

- propensity_score_weighting: output the ATE
- propensity_score_matching_treatment_to_control: output the ATT
- linear_regression: output coefficient of variable of interest
- instrumental_variable: output coefficient
- matching: output the ATE
- difference_in_differences: output coefficient
- regression_discontinuity_design: output coefficient
- linear_regression / difference_in_means: output coefficient / DiM

Response: The final answer should include a structured summary with the following fields (use "NA" where not applicable):

- Method
- Causal Effect
- Standard Deviation
- Treatment Variable
- Outcome Variable
- Covariates
- Instrument / Running Variable / Temporal Variable
- Results of Statistical Test
- Explanation for Model Choice
- Regression Equation

771

Veridical Prompt

You are an expert in statistics and causal reasoning. You will use a rigorous scientific framework to answer a causal question using a structured, step-by-step process with checklists.

Problem Statement: self.query

Step 1: Domain Understanding - What is the real-world question? Why is it important? - Could alternate formulations impact the final result?

Step 2: Dataset Overview - Dataset Path: dataset_path - Description: dataset_description - Dataset Summary, Types, Missing Values, Preview Rows

Checklist: - How was data collected? Design principles? - What are the variables, types, and units? - Are there errors or pre-processing artifacts?

Step 3: Exploratory Analysis - Identify confounders, mediators, biases - Suspect endogeneity? What instruments might be relevant? - Are strong correlations present?

Step 4: Modeling Strategy - Choose 3 candidate methods (e.g., matching, regression, IV) - State assumptions and reasons for each method - Discuss software libraries to be used and potential pitfalls - Outline key outputs and steps in analysis

Step 5: Post Hoc Analysis - Are relationships or outcomes unexpected? - Assess result stability and robustness

Step 6: Interpretation and Reporting Final Answer: Report the following fields: - Method, Causal Effect, Standard Deviation - Treatment and Outcome Variables - Covariates, Instruments or Temporal Elements - Results of any statistical tests - Justification of model choice - Equation or summary used
