

INSTATRAN: ADAPTIVE TRAINING VIA ULTRA-FAST NATURAL ANNEALING WITHIN DYNAMICAL SYSTEMS

Anonymous authors

Paper under double-blind review

ABSTRACT

Time-series modeling is broadly adopted to capture underlying patterns and trends present in historical data, allowing for prediction of future values. However, one crucial aspect in such modeling is often overlooked: in highly dynamic environments, data distributions can shift drastically within a second or less. Under this circumstance, traditional predictive models, even online learning methods struggle to adapt to the ultra-fast and complex distribution shift present in highly dynamic scenarios. To address this, we propose **InstaTrain**, a novel learning paradigm that enables frequent model updates with microsecond-level intervals for real-world prediction tasks, allowing it to keep pace with rapidly evolving data distributions. In this work, (1) We transform the slow and expensive model training process into an ultra-fast natural annealing process that can be carried out on a dynamical system. (2) Leveraging a recently proposed electronic dynamical system, we augment the system with a parameter update module, extending its capabilities to encompass both rapid training and inference. Experimental results across highly dynamic datasets demonstrate that our method delivers on average, a significant $\sim 4,000\times$ training speedup, $\sim 10^5\times$ reduction in training energy costs, and a remarkable lower test MAE over SOTA methods running on GPUs without / with the online learning mechanism.

1 INTRODUCTION

Time-series prediction lies at the heart of artificial intelligence, powering applications ranging from weather forecast (Karevan & Suykens, 2020; Hewage et al., 2020) to product and content recommendation (Kang & McAuley, 2018; Zhang et al., 2021). Current neural network methods have achieved remarkable success by learning the joint distribution between inputs and predictions (Lim & Zohren, 2021; Patton, 2013). However, these methods often implicitly assume that the learned joint distribution remains stable over a considerably long period, an assumption that can easily be violated when the underlying distribution undergoes severe shifts, consequently causing significant failures in pre-trained models. In response to this challenge, the community has pivoted towards more adaptive learning strategies, such as online learning and continual learning approaches (Hoi et al., 2021; Chen et al., 2021; He & Sick, 2021; Prabowo et al., 2023). These methodologies are designed to incrementally adjust model parameters, thereby maintaining alignment with current data trends. Despite their advancements, they struggle to adapt to the circumstances in which data distribution evolves rapidly due to their insufficient adaptation speed. This underscores the pressing need for even more agile and responsive learning mechanisms that can swiftly adapt to shifts in data distribution and ensure model effectiveness.

In the post-Moore’s Law era, the limitations of speed improvements in digital processors (such as CPUs and GPUs) have become more pronounced, attracting growing attention in novel computing substrates that harness natural power, a promising yet largely untapped area of research. As a promising candidate, a recently emerged electronic dynamical system (Afoakwa et al., 2021; Sharma et al., 2022) stands out, demonstrating the capability to support ultra-fast computing due to its remarkable low power consumption and exceptionally fast computational speed. Rooted in statistical physics, the behavior of the system is governed by its Hamiltonian (energy function), similar to natural dynamical systems where particles naturally move toward lower energy states. In the electronic dynamical system, lower energy states are rapidly reached through **natural annealing** – the auto-

matic movement of electrons among capacitors seeking equilibrium at “speed of electrons”, with minimal power consumption in milliwatt-scale.

However, despite this system having been utilized to accelerate graph learning inference in previous work (Wu et al., 2024), the model training process still relies on traditional digital processors, where the training speed falls short of keeping pace with rapidly evolving data distributions in real-world applications. Consequently, a more advanced learning paradigm is critically needed to fully exploit the potential of the dynamical system that taps into nature’s computing power. Since the system specializes in performing natural annealing, we can address the stringent agility demands for ultra-rapid model learning if we can transform the sluggish offline-training process into the natural annealing process. This idea is inspired by the Forward-Forward Algorithm proposed by Hinton (2022), which advocates for conducting both training and inference on the same hardware, similar to the way brains function. This unified approach, known as “mortal computation”, is expected to offer significantly lower costs compared to traditional neural networks running on digital hardware.

In response to this opportunity, we propose **InstaTrain**, which extends the extraordinary computational efficiency of the electronic dynamical system from inference to training, addressing the need for capturing rapidly evolving data distributions. The overall framework of this approach is illustrated in Fig. 1, comprising two major components. **(1) Training Algorithm:** Formulated as a dynamical system, our model is determined by the trainable parameters in the Hamiltonian, or energy function. The proposed algorithm accomplishes training through an iterative natural annealing process, which pushes the lowest energy state of the dynamical system to match the ground truth provided by training data. **(2) Hardware Augmentation:** We enhance the dynamical system with parameter update modules to realize a self-training mechanism. This allows both training and inference to be carried out on the same dynamical system, resulting in outstanding computational efficiency and essentially, achieving real-time model adaptation upon highly dynamic data distributions.

The core contributions of this paper can be summarized as follows:

- We propose InstaTrain, a novel learning paradigm that directly responds to the demands for agility and responsiveness in applications with fast evolving distributions.
- We transform the training of a nature-based processor into an iterative natural annealing process within the dynamical system, which enables ultra-fast model training and updating.
- We augment the original nature-based processor, extending its capabilities from fast inference to encompass both rapid training and inference.
- Experimental results across three highly dynamic datasets show that the proposed method with $\sim 1\text{W}$ power delivers a significant $\sim 3,000\times$ inference speedup, $\sim 4,000\times$ training speedup, $\sim 10^5\times$ energy cost reduction in training, and a remarkable lower test MAE over SOTA methods running on GPUs without /with dynamic model updating.

2 BACKGROUND

Ising-Based Hamiltonian. In previous work (Wu et al., 2024), the Hamiltonian function is derived from the classic binary Ising Hamiltonian (Cipra, 1987) rooted in ferromagnetism physics, but extends its formulation to overcome the limitations of binary variables (aka spins) restricted to values of $+1$ or -1 . Specifically, the binary limitation of the Ising model refers to the failure of naively extending its binary nodes to real values. The Hamiltonian of binary Ising model is $\mathcal{H}(\sigma) = -\sum_{i \neq j}^N J_{ij} \sigma_i \sigma_j - \sum_i^N h_i \sigma_i$. If σ are real-valued, they evolve to $\pm\infty$ to pursue the lowest energy state, which is $-\infty$. Even if boundaries are applied to σ , σ are only intercepted along their way to infinity, resulting in polarized nodes and essentially a binary model. To resolve this, Wu et al.

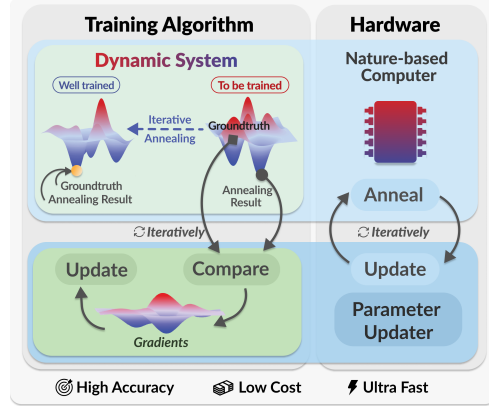

Figure 1: Overview of InstaTrain framework.

(2024) replaces the linear term in the original Hamiltonian with a pure quadratic term as follows:

$$\mathcal{H}(\mathbf{s}) = - \sum_{i \neq j}^N J_{ij} \sigma_i \sigma_j + \sum_i^N h_i \sigma_i^2, \sigma_i \in \mathbb{R}, \quad (1)$$

where $\mathbf{s} = \{\sigma_1, \sigma_2, \dots, \sigma_N\}$ denotes the spins in the dynamical system governed by the Hamiltonian, J_{ij} represents the relationship between spin σ_i and spin σ_j , and h_i refers to the self-reaction strength and is forced positive. The quadratic term acts as an energy regulator, which prevents the energy from going down to $-\infty$, allowing spins to be localized at certain values. This extension grants variables the ability to take on real values, thus making it feasible to perform more precise modeling of real-valued systems in real life. In this work, the Hamiltonian supporting real-valued variables is employed (i.e., Eq. 1).

The Electronic Dynamical System. To realize the spontaneous energy decrease feature, the electronic dynamical system Afoakwa et al. (2021) is employed as a physical embodiment of the model. In the system, the spin dynamics is designed as $d\sigma_i/dt \propto -\partial\mathcal{H}/\partial\sigma_i$ to satisfy:

$$\frac{d\mathcal{H}}{dt} = \sum_i^N \frac{\partial\mathcal{H}}{\partial\sigma_i} \frac{d\sigma_i}{dt} = - \sum_i^N \frac{1}{C} \left(\frac{\partial\mathcal{H}}{\partial\sigma_i} \right)^2 \leq 0; \quad \frac{d\sigma_i}{dt} = \frac{1}{C} \left(\sum_{j \neq i}^N (J_{ij} + J_{ji}) \sigma_j - 2h_i \sigma_i \right) \quad (2)$$

where the positive constant C is capacitance. Additionally, variables σ are modeled as voltages on capacitors, with J and h as conductance of resistors. The spin dynamics indicates that the value of a variable σ_i is influenced by input electric currents $(J_{ij} + J_{ji})\sigma_j$ and local current $2h_i\sigma_i$, charging or discharging the capacitors at “speed of electrons”.

Offline Hamiltonian Training. To train the parameters J and h in \mathcal{H} , prior research (Wu et al., 2024) employed a conditional likelihood method on traditional digital processors. This approach focuses on one spin σ_i at a time, treating other spins σ_j as conditions. An estimated spin value is:

$$\hat{\sigma}_i = \frac{1}{2h_i} \sum_{j \neq i}^N (J_{ij} + J_{ji}) \sigma_j. \quad (3)$$

After estimating each spin’s value, their differences from ground truths are evaluated using metrics such as MAE and MSE. By using these metrics as loss functions, the model parameters are optimized to align the ground truth with the system’s lowest energy state. Consequently, during inference, the inherent process of spontaneous energy decrease drives the system toward the lowest energy state, producing the desired solution with the highest probability.

3 METHODOLOGY: INSTATRAN

In this section, we present InstaTrain, a novel learning paradigm that leverages the natural annealing process of a dynamical system to enable ultra-fast model training, capturing rapidly evolving data distribution for prediction tasks. We first introduce our Iterative Natural Annealing based Training (INAT) algorithm, including how to formulate the prediction problem using the dynamical system and the detailed training process of the Hamiltonian parameters through iterative natural annealing. Furthermore, we redesign the original the electronic dynamical system, integrating update modules to enable the self-training feature.

3.1 ITERATIVE NATURAL ANNEALING BASED TRAINING (INAT)

3.1.1 FORMULATING PREDICTION VIA NATURAL ANNEALING

Our task of time-series prediction is to learn a function f_θ that maps the historical variable states \mathbf{s}^t of a system to its future states \mathbf{s}^{t+1} , i.e., $\mathbf{s}^{t+1} = f_\theta(\mathbf{s}^t)$. The goal is to optimize parameters θ such that f_θ accurately captures the system’s evolution over time.

To achieve the goal, we model the described prediction problem using the Hamiltonian of a dynamical system, with \mathbf{s}^t and \mathbf{s}^{t+1} representing the spin configurations of the dynamical system in consecutive time steps. Without loss of generality, we clamp the first $N/2$ spin values to the input

state $(\sigma_1, \dots, \sigma_{N/2}) = \mathbf{s}^t$, and aim to get the values of the remaining $N/2$ spins $(\sigma_{N/2+1}, \dots, \sigma_N)$. If the model's parameters J and h perfectly capture the dependencies between inputs and predictions, the ground truth configuration $\mathbf{s}^* = (\mathbf{s}^t, \mathbf{s}^{t+1})$ corresponds to the lowest energy of the dynamical system. Consequently, by clamping the input spins to \mathbf{s}^t and allowing the remaining spins to evolve according to the Hamiltonian \mathcal{H} , the natural annealing process will drive the system to chase equilibrium, resulting in the remaining spins moving towards the desired solution \mathbf{s}^{t+1} .

We can further interpret this annealing process using the Boltzmann distribution, which defines a mapping from energy to probability. Specifically, the lowest energy spin configuration corresponds to the maximum probability state through the following:

$$p_{\mathbf{s}^*} = \frac{1}{Z} e^{-\mathcal{H}(\mathbf{s}^*)}, \quad (4)$$

where Z is the partition function defined as $\int e^{-\mathcal{H}} d\sigma$, functioning as a normalizing constant. Therefore, the system's evolution towards the lowest energy state is equivalent to finding the desired prediction \mathbf{s}^{t+1} with the highest probability under the Hamiltonian \mathcal{H} . To elucidate more clearly, we visualize the whole process in Fig. 2. Clamping the input \mathbf{s}^t confines the entire energy landscape to a subspace compatible with the given input data. The remaining unclamped spins then undergo natural annealing within this constrained landscape, spontaneously evolving towards the lowest energy state, yielding the desired solution \mathbf{s}^{t+1} . Notably, a physical system governed by its energy function \mathcal{H} can spontaneously evolve towards its lowest energy configuration through natural annealing, leveraging the full parallelism of the underlying physical dynamics.

Figure 2: Prediction via annealing

3.1.2 TRAINING THROUGH ITERATIVE NATURAL ANNEALING

Through the above description, we can perform efficient prediction on the dynamical system given the optimal Hamiltonian parameters J and h . In terms of training, instead of undergoing costly training processes on digital processors, it is much more preferable that model training is also available on the dynamical system. To address this, we describe how to obtain the target parameters from the training data through an iterative natural annealing process, the same process used for inference.

Specifically, we seek to maximize the likelihood of the training set under the model:

$$\arg \max_{J, h} \prod_{\mathbf{s} \in T} p_{\mathbf{s}}, \quad (5)$$

where T is the training set constructed as $\mathbf{s} = (\sigma_1, \dots, \sigma_N) = (\mathbf{s}^t, \mathbf{s}^{t+1})$. This is equivalent to minimizing the negative log-likelihood loss:

$$\arg \min_{J, h} \mathcal{L}(\mathbf{s}; J, h) = \frac{1}{M} \sum_{\mathbf{s} \in T} (\ln(Z) - \ln(e^{-\mathcal{H}})), \quad (6)$$

where M is the number of training samples. Thus, the gradients of \mathcal{L} with respect to J_{ij} are given by

$$\frac{\partial \mathcal{L}(\mathbf{s})}{\partial J_{ij}} = \frac{\partial \ln(Z)}{\partial J_{ij}} + \frac{1}{M} \sum_{\mathbf{s} \in T} \frac{\partial \mathcal{H}}{\partial J_{ij}}, \quad (7)$$

where the two terms are essentially expectations of spin multiplications:

$$\frac{\partial \ln(Z)}{\partial J_{ij}} = \frac{1}{Z} \frac{\partial Z}{\partial J_{ij}} = \frac{\int e^{-\mathcal{H}} \sigma_i \sigma_j d\sigma}{\int e^{-\mathcal{H}} d\sigma} = \langle \sigma_i \sigma_j \rangle_{\text{model}}, \quad \frac{1}{M} \sum_{\mathbf{s} \in T} \sigma_i \sigma_j = \langle \sigma_i \sigma_j \rangle_{\text{data}}. \quad (8)$$

Particularly, $\langle \sigma_i \sigma_j \rangle_{\text{data}}$ denotes the expectation over the training data, which is tractable, and $\langle \sigma_i \sigma_j \rangle_{\text{model}}$ corresponds to the expectation of $\sigma_i \sigma_j$ given by the current model. Consequently, the gradient for the coupling parameter J_{ij} is

$$\frac{\partial \mathcal{L}(\mathbf{s})}{\partial J_{ij}} = \langle \sigma_i \sigma_j \rangle_{\text{model}} - \langle \sigma_i \sigma_j \rangle_{\text{data}}. \quad (9)$$

Figure 3: Model training through iterative natural annealing

In the same way, the gradients of h_i are given by

$$\frac{\partial \mathcal{L}(\mathbf{s})}{\partial h_i} = \frac{\partial \ln(Z)}{\partial h_i} + \frac{1}{M} \sum_{\mathbf{s} \in T} \frac{\partial \mathcal{H}}{\partial h_i} = \frac{\partial \ln(Z)}{\partial h_i} + \frac{1}{M} \sum_{\mathbf{s} \in T} \sigma_i^2 = -\langle \sigma_i^2 \rangle_{\text{model}} + \langle \sigma_i^2 \rangle_{\text{data}}. \quad (10)$$

Therefore, to update the parameters, we need to calculate $\langle \sigma_i \sigma_j \rangle_{\text{model}}$ and $\langle \sigma_i^2 \rangle_{\text{model}}$. They correspond to the expectation of a large number of states under the current model parameters, which requires computationally expensive sampling over the model distribution. Instead of employing expensive sampling methods to estimate $\langle \cdot \rangle_{\text{model}}$, we leverage the intrinsic dynamics of the electronic system to achieve remarkable efficiency. As described in §3.1.1, we can obtain the current model’s prediction $\hat{\mathbf{s}}^{t+1}$ through clamping \mathbf{s}^t to input spins and allowing the dynamical system to perform natural annealing. By measuring the spin configurations at the end of the annealing process, we can directly calculate the required model expectations $\langle \sigma_i \sigma_j \rangle_{\text{model}}$ and $\langle \sigma_i^2 \rangle_{\text{model}}$. In this way, the training process is transformed into an iterative natural annealing process, as described in Algorithm 1 and illustrated in Fig. 3. This innovative training process eliminates the need for computationally expensive sampling techniques or digital offline training. Instead, it harnesses the natural energy decrease feature to perform efficient computations, enabling ultra-fast model training.

Algorithm 1 Iterative Natural Annealing-based Training

Input: Training set $T = \{\mathbf{s}_1, \mathbf{s}_2, \dots, \mathbf{s}_M\}$, initial J^0, h^0 , learning rate η , and training epochs N_{iter} .

Output: Trained Hamiltonian parameters J, h .

```

1: Initialize  $J \leftarrow J^0, h \leftarrow h^0$ .
2: for  $i = 1$  to  $N_{\text{iter}}$  do
3:   for each  $\mathbf{s}_j = (\mathbf{s}_j^t, \mathbf{s}_j^{t+1})$  in  $T$  do
4:     Clamp the first half spins to  $\mathbf{s}_j^t$ 
5:     Perform natural annealing to obtain  $\hat{\mathbf{s}}_j^{t+1}$ 
6:     Get  $\langle \sigma_i \sigma_j \rangle_{\text{model}}$  and  $\langle \sigma_i^2 \rangle_{\text{model}}$  based on  $\mathbf{s}_j^t, \hat{\mathbf{s}}_j^{t+1}$ 
7:     Get  $\langle \sigma_i \sigma_j \rangle_{\text{data}}$  and  $\langle \sigma_i^2 \rangle_{\text{data}}$  based on  $\mathbf{s}_j^t, \mathbf{s}_j^{t+1}$ 
8:     Update  $J_{ij} \leftarrow J_{ij} - \eta \cdot (\langle \sigma_i \sigma_j \rangle_{\text{model}} - \langle \sigma_i \sigma_j \rangle_{\text{data}})$ 
9:     Update  $h_i \leftarrow h_i - \eta \cdot (-\langle \sigma_i^2 \rangle_{\text{model}} + \langle \sigma_i^2 \rangle_{\text{data}})$ 
10:  end for
11: end for
12: return  $J, h$ 

```

To summarize, the outcome of the natural annealing process depends on the accuracy of the current Hamiltonian parameters in capturing the dependencies between the inputs and predictions. When the values of some spins are fixed to \mathbf{s}^t , two scenarios can occur: (1) If the parameters properly describe the dependencies, the annealing process will converge to the desired solution \mathbf{s}^{t+1} , representing the ideal case where the model has successfully learned the correct relationships between the inputs and predictions. (2) If the parameters do not accurately capture these dependencies, the annealing process will instead yield results that align with the current model’s expectations, denoted by $\langle \sigma_i \sigma_j \rangle_{\text{model}}$ and $\langle \sigma_i^2 \rangle_{\text{model}}$. This outcome indicates that the model’s parameters require further optimization to better represent the underlying dependencies. Regardless of the parameter accuracy, both scenarios correspond to the equilibrium state of the dynamical system.

3.2 HARDWARE AUGMENTATION

The physical realization of this dynamical system is achieved by mapping the spin values to the voltages applied on nano-scale capacitors C , and modeling the Hamiltonian parameters J and h as the conductance of resistors. More specifically, referring to Fig. 4, the value of the spin σ_i corresponds to the voltage V_i , the effective conductance of the coupling between spin σ_i and spin σ_j is J_{ij} (yellow blocks). The effective conductance of the added variable resistor for spin σ_i is $2h_i$, which is embedded in nodes. This mapping enables the construction of the dynamical system using a mesh of programmable resistors, which are interconnected and span across all spins. By exploiting the intrinsic dynamics (Eq. 11) of this resistor-capacitor network, the natural annealing process (energy decrease) can be physically implemented, allowing for rapid convergence towards the equilibrium state that corresponds to the desired solutions, or the model’s expectations.

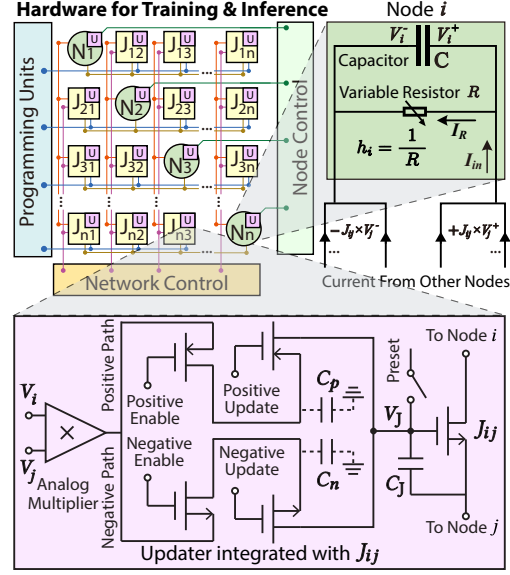

Figure 4: Redesigned *InstaTrain* hardware.

$$C \frac{dV_i}{dt} = - \frac{\partial \mathcal{H}}{\partial V_i} = \sum_{j \neq i} (J_{ij} + J_{ji}) V_j - 2h_i V_i = I_{in} - I_R. \quad (11)$$

After the natural annealing process is implemented in this electronic system, we need to further make the system self-trainable. Compared to the original system, update modules need to be implemented. In particular, the update modules take the values of spins σ_i and σ_j as input, compute $V_i V_j$, and update the voltage V_J applied to the capacitor C_J . A programmable parameter J_{ij} is then updated according to the value of V_J . As depicted in Fig. 4, we embed the update modules (shown as purple blocks) in coupling units (for updating J_{ij}) and nodes (for updating h_i). The detailed steps are:

1. Initialize J_{ij} through preset, giving V_J an initial value.
2. Initialize V_i and V_j . For an input node, load the ground truth, otherwise initialize it arbitrarily.
3. Start annealing to get the updated V_i and V_j .
4. Obtain $\langle V_i V_j \rangle_{\text{model}}$ using the analog multiplier. The result is captured in capacitors as voltages.
5. Load the ground truths of V_i and V_j .
6. Obtain $\langle V_i V_j \rangle_{\text{data}}$ as voltage using the analog multiplier.
7. Based on the voltage difference between $\langle V_i V_j \rangle_{\text{model}}$ and $\langle V_i V_j \rangle_{\text{data}}$, the positive path is enabled if the former is larger, otherwise enable the negative path.
8. The subtraction of the two voltages contributes to V_J , modifying the voltage to update J_{ij} .
9. Repeat steps (2)-(8) for the next epoch.

Through these steps, the entire training process is transformed into an iterative natural annealing process within the dynamical system, enabling ultra-fast training for highly dynamic applications.

4 EVALUATION

4.1 EXPERIMENTAL SETUP

Datasets. We evaluate InstaTrain on [five](#) high-frequency datasets, each providing 100 samples per second. *Carbon-Oxide* records the sampled concentration of a mixture of carbon oxide and ethylene (Fonollosa et al., 2015b). *Methane* records the sampled concentration of a mixture of methane and ethylene (Fonollosa et al., 2015b). *Stock* contains sampled stock data of S&P-500 (Nasdaq). *Ammonia* includes time series recordings from a chemical detection platform, featuring data from 72 metal-oxide sensors across six different locations, all maintained under consistent wind speed and operating temperatures are collected (Fonollosa et al., 2015a). *Toluene* comprises time series recordings from 72 sensors at one location, collected under ten varying conditions (two wind speeds

Table 1: Accuracy comparison across datasets. LF / HF: Low / High Frequency. Online learning methods only have HF. Gray-shaded results indicate “Not Achievable” results due to slow training.

	Dataset	Carbon-Oxide	Methane	Stock	Ammonia	Toluene
Static	Best GNN	14.40	19.31	2.85	13.43	13.26
	Best Trans	14.02	19.29	2.27	12.41	11.95
	NPGL	13.90	19.22	2.01	12.15	11.43
	InstaTrain	13.88	19.25	2.02	12.08	11.37

	InstaTrain	6.79	7.05	0.68	1.36	1.86

and five operating temperatures) from a chemical detection platform (Fonollosa et al., 2015a). The statistics of these dataset are detailed in the Table 4 in the Appendix

Baselines. We consider three types of baselines for comparison.

- Static Models: SOTA GNNs, SOTA Transformer-based time series prediction models, NP-GL (Wu et al., 2024), and InstaTrain trained with the first 25% data of each dataset. Then, these models are tested on the remaining 75% data of each dataset. The GNNs include: Graph-WaveNet (Wu et al., 2019), MTGNN (Wu et al., 2020), and MegaCRN (Jiang et al., 2023). The Transformer-based models include: Autoformer (Wu et al., 2021), DLinear (Zeng et al., 2023), iTransformer (Liu et al., 2023a).
- Low-Frequency Dynamic Models: Based on the pre-trained static models above, the GNNs, Transformer-based models, NP-GL, and InstaTrain are updated as new data becomes available, but with a lower update frequency. In particular, the models are updated once after observing 1,000 snapshots, equivalent to 10 seconds in the real world. After each update, the model is tested on the next 1,000 snapshots.
- High-Frequency Dynamic Models: Similar to low-frequency setup, but the GNNs, Transformer-based models, NP-GL, and InstaTrain are updated more frequently—once every 100 snapshots. After each update, the model is tested on the next 100 snapshots. Additionally, we include SOTA online learning models – FSNet (Pham et al., 2022), online-adapted PatchTST (Nie et al., 2022) proposed in (Wen et al., 2024), and Onenet (Wen et al., 2024). These online learning models are implemented based on their default setup for a fair comparison (updated every snapshot).

To more effectively showcase the impact of high-frequency online learning, both low-frequency and high-frequency models are updated using data from the most recent 100 snapshots in the past.

Platforms. The inference latency and accuracy of the SOTA GNNs and online learning approaches are measured using an NVIDIA A100-40GB GPU. On the same GPU, the training latency of NP-GL, GNNs, and online learning approaches are also evaluated. The accuracy and latency of InstaTrain, as well as the accuracy and inference latency of NP-GL, are measured using a CUDA-based Finite Element Analysis (FEA) software simulator implemented based on the one of BRIM (Afoakwa et al., 2021). The Cadence Mixed-signal Design Environment is used to evaluate the power and area of InstaTrain.

4.2 MAIN RESULTS

Accuracy Evaluations. In Table 1, the accuracy results are shown across five datasets with Mean Absolute Error (MAE) as the metric. The results for the dynamic models are averaged across all snapshots in test data. Here, we present the best-performing GNN and Transformer-based model

Figure 5: Average training latency per snapshot.

(Best Trans), a complete version of this table is provided in Table A.1 in the Appendix. The results demonstrate that InstaTrain outperforms the GNNs and Transformer-based models (Trans) in all three cases (static, low-frequency, and high-frequency) across all datasets, with comparable accuracy versus NP-GL. The comparison of different update scenarios indicates that high-frequency updates are necessary to achieve better performance. However, due to the sluggish training speed of NP-GL, GNNs, Trans, and even SOTA online-training methods, their high-frequency update results are not achievable, shown as the gray-shaded results in the table. This is because their training latency per snapshot exceeds 0.01 seconds (see Fig. 5), resulting in a cumulative training time of over 1 second for 100 snapshots. Consequently, they cannot keep up with the high-frequency update schedule, making real-time adaption "Not Achievable" for them in this scenario. However, for the sake of comparison, we still calculate the accuracy of these baseline models under the high-frequency setup, assuming they could meet the update schedule. The limitation of baselines makes InstaTrain the ideal choice for achieving high accuracy, especially in the cases where the speed of data distribution is ultra-fast. On average, the high-frequency result of InstaTrain achieves 75.11% MAE reduction compared to static models, and 50.53% versus low-frequency dynamic models. Despite that the baselines are not fast enough to perform high-frequency update, InstaTrain still achieves 8.42% MAE reduction compared to them.

Latency Evaluations. The average training latency per snapshot and inference latency per snapshot are illustrated in Fig. 5 and Fig. 6, both in the scale of seconds. Since the computing workloads involved in low-frequency models and high-frequency models are identical for each update – the total workload solely depends on the update frequency, we present the training result in "latency per snapshot" instead of the total training time. Fig. 5 demonstrates that InstaTrain achieves microsecond-level (10^{-6} second) update time per snapshot, in contrast to tens of milliseconds for other approaches. The red dashed line indicates the training latency requirement to achieve low-frequency model update, where all models are qualified, and can achieve the accuracy benefit brought from static learning to low-frequency online learning. However, the orange dashed line implies that all selected SOTA models except InstaTrain are not qualified for further improved accuracy in high-frequency online learning, corresponding to the "Not Achievable" gray-shaded results in Table 1. In addition, the inference latency in Fig. 6 shows that InstaTrain also benefits from the exceptional speed brought by the dynamical system, resulting a similar latency with respect to NP-GL on the prediction tasks. On average, InstaTrain can achieve a $\sim 4,000\times$ speedup in online learning versus all baseline models on all tasks, while achieving $\sim 3,000\times$ speedup in inference compared to the baselines other than NP-GL, showcasing the computing capability of a dynamical system.

Hardware Characteristics. The hardware characteristics of InstaTrain are compared to related work in Table 2. Despite higher power and area resources utilized, the power is still within the scale of 1 Watt, with comparable area with respect to prior work. More importantly, the proposed hardware supports ultra-fast online training that is performed on the same hardware as inference,

Figure 6: Average inference latency per snapshot.

Table 2: Hardware comparison with related work.

Design	Power	Area	Real-Value	Ultra-Fast Training
BRIM (Afoakwa et al., 2021)	250 mW	5 mm ²	No	No
NP-GL (Wu et al., 2024)	260 mW	5.1 mm ²	Yes	No
InstaTrain	950 mW	9.7 mm ²	Yes	Yes

Table 3: Accuracy ablation study on update interval.

Update Interval	Carbon-Oxide	Methane	Stock	Ammonia	Toluene
1000	8.28	9.22	1.20	3.72	4.67
500	7.26	8.46	0.84	2.41	3.57
100	6.79	7.05	0.68	1.36	1.86
50	6.73	7.02	0.67	1.33	1.85

resulting significantly lower overhead and orders of magnitude training speedup compared to NP-GL upgraded from BRIM. Furthermore, the speedup and the low power nature of InstaTrain collectively contribute to a significantly lower energy cost, leading to $\sim 10^5 \times$ reduction in energy consumption compared to the SOTA GNNs and online learning approaches on high-end GPUs.

Ablation Study. In practice, the update frequency is a vital hyperparameter, in order to balance the quality and speed. To investigate this, we adjust the model update frequency from every 50 snapshots to 1000 snapshots for all datasets (namely, update interval). The results are shown in Table 3, indicating that generally, high-frequency online learning results in superior accuracy (shown in MAE).

5 RELATED WORK

Ising-Based Models. Ising-based dynamical systems have gained attention in the machine learning community due to their unique properties and potential for solving complex problems. Drawing inspiration from statistical mechanics in physics, the evolution of a system is based on its energy function. The majority of studies showcasing the potential of Ising methods have been confined to relatively straightforward applications, primarily within the binary domain. For instance, the binary Ising model has been employed to formulate optimization problems (Lucas, 2014), which can be efficiently solved on specialized hardware platforms designed for the model, namely, Ising machines (Mohseni et al., 2022) (Codognot et al., 2022). Additionally, several real-world problems, such as satisfiability (SAT) problems (Sharma et al., 2023a) (Sharma et al., 2023b), traffic congestion prediction (Pan et al., 2023), uplink MIMO detection (Singh et al., 2023) and collaborative filtering (Liu et al., 2023b), have also been formulated and addressed using the binary Ising model. While they have offered valuable insights into practical problem-solving, their methods come with binary limitations that impede further progress in real-valued applications in the real world.

Although (Wu et al., 2024) extends the original binary Ising model to a real-valued Ising-based model for real-valued applications, the practical impact of their contributions is limited. Firstly, their acceleration is restricted to inference alone, leaving the primary bottleneck of training unaddressed. Secondly, the benefits of accelerated inference are diminished if the model is static and cannot be promptly updated, especially in highly dynamic applications where patterns evolve rapidly. To summarize, the slow training process hinders online learning and real-time model updates, which are crucial for adapting to fast-changing dynamics, thus limiting the real-world applicability of the proposed real-valued model in many scenarios demanding real-time adaptability and responsiveness.

Ising Machines. Solving complex combinatorial optimization problems is computationally demanding for conventional von Neumann architectures, as both the required time and hardware resources grow exponentially with the size of the problem. To solve such computationally demanding problems, drawing computing power from nature has become a research direction that attracts attention. Among the various nature-based computing approaches, Ising machines have garnered significant attention due to their ability to efficiently solve optimization problems by leveraging the principles of the Ising model from statistical physics. The Ising model describes the behavior of atoms in natural magnets or spin glasses, which can adopt one of two spin states, up or down, to achieve the lowest energy configuration. This model is applicable to various combinatorial optimization problems (Bian et al., 2010), where finding the ground energy state of the Ising model equates to solving these problems.

In addition to (Afoakwa et al., 2021), various Ising machine implementations have been proposed and developed, each with its unique characteristics and trade-offs. (1) Quantum-based Ising machines, such as the D-Wave system (Harris et al., 2010), leverage quantum effects, including quantum tunneling, using superconducting qubits. While they offer high computational speed, they require cryogenic environments to enable superconductivity, resulting in high energy consumption and limited practicality. (2) Optical Ising machines (Inagaki et al., 2016; Yamamoto et al., 2017; McMahon et al., 2016) employ optical parametric oscillators to simulate spins and achieve optical coupling. Although they provide significant parallelism, their scalability and stability are limited by their large size and sensitivity to temperature fluctuations. (3) Digital annealers (Yamaoka et al., 2015) are accelerators that perform simulated annealing on digital devices to emulate the continuous annealing process. While they achieve speeds significantly faster than general-purpose processors, their efficiency gains do not yet match those of analog Ising machines due to the substantial difference in hardware operating speed. Among these diverse technologies, the BRIM stands out as particularly promising, offering high-quality solutions rapidly and efficiently. Its operational efficiency, coupled with realistic power consumption and minimal chip area, positions BRIM as a leading candidate in the field of nature-based computing.

6 CONCLUSION

This paper presents InstaTrain, a novel approach to ultra-rapid model learning for prediction tasks. By transforming the training process into an iterative natural annealing process within a dynamical system, our method enables the model to self-evolve and autonomously adapt to the ever-changing correlations between inputs and predictions, addressing the pressing need for agility and responsiveness in highly dynamic applications. The developed parameter update modules augment the original dynamical system used only for inference, extending its capabilities to encompass both rapid training and inference, thereby harnessing the full potential of this innovative computing substrate. This pioneering approach transcends the limitations of conventional methods and paves the way for a new era of ultra-rapid, energy-efficient, and adaptive predictive modeling, empowering applications in domains characterized by high data volatility and stringent latency requirements. Further explorations could focus on incorporating hardware-accommodating advanced online learning strategies into the proposed method, which might yield better solutions. To highlight, InstaTrain achieves, on average, $\sim 4,000\times$ training speedup supporting microsecond-level model update, $10^5\times$ energy cost reduction in training, as well as a remarkable lower MAE over SOTA methods without / with online learning features.

REPRODUCIBILITY

The GPU-based emulator of the dynamical system processor will be open-sourced, enabling the reproducibility of this work and open research in this field.

A APPENDIX

This appendix provides additional experimental results and discussions related to our work.

A.1 DATASET STATISTICS AND EXPERIMENTAL RESULTS

Table 4 summarizes the statistics of the datasets used in our experiments.

Table 4: Dataset statistics

Dataset	Carbon-Oxide	Methane	Stock	Ammonia	Toluene
# of Samples	60000	60000	40060	12755	12854
# of Nodes	16	16	116	432	720

Additionally, the complete version of Table 1 is provided below for reference.

Table 5: Accuracy comparison across datasets. LF / HF: Low / High Frequency. Online learning methods only have HF. Gray-shaded results indicate “Not Achievable” results due to slow training.

	Dataset	Carbon-Oxide	Methane	Stock	Ammonia	Toluene
Static	GWN	14.40	19.34	3.34	19.35	13.26
	MTGNN	24.47	19.31	2.85	13.43	18.74
	MegaCRN	25.94	23.65	3.45	18.12	20.15
	Informer	14.16	19.37	2.76	13.59	13.07
	DLinear	14.08	19.32	2.31	12.74	12.82
	iTransformer	14.02	19.29	2.27	12.41	11.95
	NPGL	13.90	19.22	2.01	12.15	11.43
	InstaTrain	13.88	19.25	2.02	12.08	11.37
LF Update	GWN	10.28	11.84	1.85	4.72	5.82
	MTGNN	12.51	11.57	1.70	4.95	5.19
	MegaCRN	12.34	13.49	1.87	5.41	5.93
	Informer	9.21	10.41	1.64	4.39	5.25
	DLinear	8.82	10.25	1.39	4.16	4.96

A.2 ENERGY EVOLUTION OF THE DYNAMICAL SYSTEM

We present a visualization of the system’s energy with respect to annealing time for a sample from the Carbon-Oxide dataset during inference in Fig. 7. The energy curve clearly demonstrates a convergence pattern, with the system’s energy rapidly decreasing and stabilizing over time as it approaches equilibrium. Furthermore, we introduce perturbations at an annealing time of $0.6e-7s$ by adding Gaussian noise to the nodes at levels of 10% (blue curve), 20% (green curve), and 30% (red curve). These perturbations further confirm that the system can achieve equilibrium, as it returns to a stable state even when subjected to varying degrees of disturbance.

Figure 7: System energy with respect to annealing time.
