## ABSTRACT

Graph Neural Networks (GNNs) have achieved state-of-the-art performance on tasks such as user-item interaction prediction in recommender systems, molecular property classification, and credit risk scoring and fraud detection in financial risk modeling. However, their opaque embedding mechanisms raise critical concerns about transparency and trustworthiness. Existing explainability approaches largely focus on identifying the nodes, edges, or subgraphs that influence the model’s prediction but fail to disentangle how individual node features shape learned embeddings. In this work, we propose a novel decomposition framework that systematically attributes each embedding to original node and/or edge features. We qualitatively demonstrate the framework on Graph Convolutional Networks (GCN) and Heterogeneous GraphSAGE (HinSAGE) using Cora and MovieLens, and quantitatively benchmark against widely adopted baselines across multiple datasets. Results indicate that our approach improves interpretability by revealing how node features contribute to individual graph embeddings and clarifying the role of neighborhood aggregation in shaping predictions. This work connects structural explainability and feature-level attribution, providing a principled foundation for trustworthy and actionable GNN explanations.<sup>1</sup>

## 1 INTRODUCTION

Graph Neural Networks (GNNs) have established themselves as powerful models for relational and structured data, achieving state-of-the-art performance in fields ranging from molecular property prediction to recommender systems to financial risk analysis. Such models leverage both the features of the entities represented by nodes and the connections between them, as well as the structure of the graph created by these relationships. However, their black-box nature has raised concerns about transparency and accountability, spurring a growing literature on explainability of GNNs. Recent surveys (Yuan et al., 2023; Kakkad et al., 2023) provide comprehensive taxonomies of this work, categorizing methods into post-hoc attribution techniques, model-specific explainers, and inherently interpretable architectures. Despite this progress, transparently explaining the node feature information captured in GNN embeddings remains an open question.

Much of the early work focused on structural explanations, identifying which nodes, edges, or subgraphs are most influential for a given prediction. Methods such as GNNExplainer (Ying et al., 2019) and PGExplainer (Luo et al., 2020) learn masks to highlight critical subgraphs, while approaches like SubgraphX (Yuan et al., 2021) employ Monte Carlo search to locate and extract task-relevant structures. Perturbation-based methods extend this idea by quantifying the importance of nodes or edges through controlled modifications of the graph. These approaches have proven valuable in identifying important structures, but do not provide insight into the node features captured by the GNNs.

In parallel, researchers have adapted gradient- and propagation-based methods from computer vision, such as Integrated Gradients (IG), Layer-wise Relevance Propagation, and GraphLRP, to trace

<sup>1</sup>The views expressed in this paper are solely those of the authors and do not necessarily reflect the views of their affiliated institutions.

054 attribution signals back through GNN layers(Pope et al., 2019; Baldassarre & Azizpour, 2019;  
 055 Schnake et al., 2021). These methods provide finer-grained insights into node features, yet they of-  
 056 ten conflate structural and feature importance due to message passing. Moreover, their dependence  
 057 on local gradient signals makes them highly sensitive to noise, unstable under small perturbations,  
 058 and prone to correlation bias. More principled frameworks, including counterfactual and causal ex-  
 059 planations, have emerged to assess how hypothetical perturbations affect predictions. For instance,  
 060 CF-GNNExplainer (Lucic et al., 2022) perturbs adjacency matrices to find the minimal perturbation  
 061 to the input graph such that the prediction changes. However, these approaches also remain primarily  
 062 concerned with structural or instance-level contributions rather than the feature-level decomposition  
 063 of embeddings.

064 More recent work has expanded the landscape. For example, DEGREE (Feng et al., 2023) decom-  
 065 poses GNN mechanisms to attribute predictions to subgraph components, and D4Explainer (Chen  
 066 et al., 2023) introduces in-distribution explanations through diffusion-based counterfactuals. DyEx-  
 067 plainer (Wang et al., 2023) extends interpretability to dynamic GNNs by capturing temporal depen-  
 068 dencies, while GraphOracle (Du et al., 2025) provides self-explainable class-level subgraphs without  
 069 requiring post-hoc search. Other advances include FIGNN (Raut et al., 2025), which emphasizes  
 070 feature-specific interpretability. At the same time, evaluation frameworks like GraphXAI (Agar-  
 071 wal et al., 2023) have benchmarked existing explainers, while robustness studies have highlighted  
 072 their fragility to adversarial perturbations. In terms of interpretability of node embeddings, Dalmia  
 073 & Gupta (2018) first analyzed how embedding dimensions correlate with basic graph properties,  
 074 revealing implicit structural signals. Piaggesi et al. (2024) introduced DINE, which restructures  
 075 embeddings for dimensional interpretability, ensuring each dimension reflects meaningful substruc-  
 076 tures. Extending this idea, Piaggesi et al. (2025) developed a disentangled, self-explainable repre-  
 077 sentation learning approach that enforces semantic separation across dimensions.

078 Despite these advancements, there remains a lack of methods that systematically decompose a tar-  
 079 get node’s final embedding into contributions from individual features of the nodes, edges, and  
 080 their neighbors. In applications where speed or infrastructure concerns are critical, learned graph  
 081 embeddings may be used to capture the information learned by a GNN and fed into downstream  
 082 predictive systems. There, they act as engineered features to boost performance over models with  
 083 only observed features. These embeddings capture the underlying structural relationships and fea-  
 084 ture interactions within the graph, summarizing multi-hop dependencies and relational patterns into  
 085 compact representations, incorporating the influence of neighbors on outcomes. While this practice  
 086 produces clear performance gains, it also raises accountability challenges: if embeddings drive de-  
 087 cisions in sensitive contexts such as credit risk assessments, fraud detection, or medical diagnosis,  
 088 then stakeholders should be able to trace which node and edge features shaped these embeddings  
 089 and to what degree. For instance, in a fraud detection scenario, graph embeddings may increase  
 090 a model’s ability to detect fraud, but it is critical to understand which properties of the consumer,  
 091 transaction, and merchant were captured by the GNN in order to understand evolving fraud patterns  
 092 and develop mitigation strategies.

093 Motivated by this gap, this paper introduces a novel method for feature-wise decomposition of em-  
 094 beddings, enabling fine-grained attribution that complements structural explanations. By explicitly  
 095 accounting for correlations among features, our method provides a faithful mechanism to trace how  
 096 information is transformed through GNN layers into the target embedding representation. This re-  
 097 veals what node information is captured by the graph embeddings, thereby aligning predictive power  
 098 with the demands of accountability and interpretability in high-stakes domains. Table 1 summarizes  
 099 the capabilities of representative GNN explanation methods. While prior approaches can attribute  
 100 predictions to node features or edges, they generally do not explain embeddings, and most rely  
 101 on optimization, sampling, or architecture-specific constraints. Our decomposition framework is  
 102 unique in directly tracing embeddings back to raw features, supporting aggregation across embed-  
 103 dings, and producing deterministic, efficient attributions through simple matrix multiplications.

104 The remainder of this work is structured as follows. In Section 2, we present our decomposition  
 105 framework for inverting embedding generation in GNNs and demonstrate its application on two  
 106 representative architectures: Graph Convolutional Network (GCN) and Heterogeneous GraphSAGE  
 107 (HinSAGE). Section 3 illustrates the approach empirically using the Cora citation network (Sen  
 et al., 2008) for node classification to demonstrate feature-wise decomposition for GCN embeddings,  
 and the MovieLens dataset (Harper & Konstan, 2015) for link regression to highlight type-aware and

edge-level explanations in HinSAGE. Section 5 discusses implications, limitations, and potential extensions of our method. Finally, Section 6 concludes the paper.

## 2 METHOD

We propose a framework for decomposing graph neural network (GNN) embeddings into feature-wise contributions. The central observation is that, once the nonlinearity from the architecture is fixed (e.g., ReLU with a given input), each GNN layer becomes a linear operator for that input. This allows us to propagate contributions of node and edge features through successive layers and exactly reconstruct each output embedding as a sum over these features. We illustrate the framework with two widely used architectures: the Graph Convolutional Network (GCN) (Kipf & Welling, 2017) for node classification and Heterogeneous GraphSAGE (HinSAGE) (Hamilton et al., 2017; Ying et al., 2018; Zhang et al., 2019) for heterogeneous link prediction. For clarity, we summarize the notation used in Table 3.

### 2.1 GENERAL FRAMEWORK

A message-passing GNN layer that uses the relational graph convolutional operator (Schlichtkrull et al., 2018) can be expressed as follows:

$$\mathbf{h}_v^{(\ell)} = \sigma \left( W_{\text{self}}^{(\ell)} \mathbf{h}_v^{(\ell-1)} + \sum_{r \in \mathcal{R}} W_r^{(\ell)} \mathcal{A}_r(\{\mathbf{h}_u^{(\ell-1)} : u \in N_r(v)\}) + \mathbf{b}^{(\ell)} \right),$$

where  $\mathcal{A}_r$  is a *linear aggregator* (e.g., normalized sum, mean, or sampled mean) and  $\mathcal{R}$  indexes edge types or relations.

To invert this process, we propagate *contribution matrices* in parallel to the forward pass. Initialization is  $\mathbf{C}_{w \rightarrow v}^{(0)} = \mathbf{x}_w^\top$  if  $w = v$ , and 0 otherwise. Propagation is then

$$\mathbf{C}_{\cdot \rightarrow v}^{(\ell+1)} = D_v^{(\ell)} \left( W_{\text{self}}^{(\ell)} \mathbf{C}_{\cdot \rightarrow v}^{(\ell)} + \sum_{r \in \mathcal{R}} W_r^{(\ell)} \mathcal{A}_r(\{\mathbf{C}_{\cdot \rightarrow u}^{(\ell)} : u \in N_r(v)\}) + \mathbf{b}^{(\ell)} \right),$$

where  $D_v^{(\ell)}$  is a diagonal matrix that encodes the activation pattern for the given input for node  $v$  at layer  $\ell$ . After  $L$  layers,  $\mathbf{h}_v^{(L)}$  can be exactly decomposed as a sum over  $\{\mathbf{C}_{w \rightarrow v}^{(L)}\}$ , with each term corresponding to a source node  $w$  and input feature dimension  $p$ . Contribution vectors can be summarized into scalar importance scores using norms, and can also be projected for visualization using a PCA-based method (see Appendix for details).

### 2.2 GRAPH CONVOLUTIONAL NETWORKS (GCN)

The Graph Convolutional Network (GCN) (Kipf & Welling, 2017) is an adjacency-based GNN widely used for semi-supervised node classification. For two-layer GCN, each layer applies normalized adjacency  $\tilde{A} = D^{-\frac{1}{2}}(A + I)D^{-\frac{1}{2}}$  to mix neighbor features:

$$\mathbf{H}^{(1)} = \sigma(\tilde{A}XW^{(0)} + \mathbf{b}^{(0)}), \quad \mathbf{H}^{(2)} = \sigma(\tilde{A}\mathbf{H}^{(1)}W^{(1)} + \mathbf{b}^{(1)}).$$

162 For a target node  $v$ , the contribution from feature  $p$  of node  $w$  to the embedding  $\mathbf{h}_v^{(2)}$  is  
 163

$$164 \quad [C_{w \rightarrow v}^{(2)}]_{p,:} = D_v^{(1)} \left( \sum_{u \in \mathcal{V}} \tilde{A}_{vu} D_u^{(0)} (\tilde{A}_{uw} \mathbf{x}_w[p] \mathbf{e}_p^\top W^{(0)} + \mathbf{b}^{(0)}) W^{(1)} \right). \quad (1)$$

165  
 166  
 167

This expansion shows that signals propagate along paths  $w \rightarrow u \rightarrow v$ . Self-contributions arise when  $w = v$ , first-hop contributions when  $w \in N(v)$ , and two-hop contributions when  $w$  connects via some  $u$ . Grouping terms provides hop-level or self/neighbor breakdowns of the learned representation.  
 171

### 172 2.3 HETEROGENEOUS GRAPHSAGE (HINSAE) 173

174 GraphSAGE (Hamilton et al., 2017) is a widely used inductive GNN framework that learns node  
 175 embeddings by sampling and aggregating information from each node’s neighborhood. Hin-  
 176 SAGE (Ying et al., 2018; Zhang et al., 2019) generalizes GraphSAGE to heterogeneous graphs  
 177 with multiple node and edge types. Instead of operating with a full adjacency matrix, it samples  
 178 fixed-size neighborhoods per hop, stratified by type. Each neighbor type has its own projection  
 179 matrix. For node  $v$  of type  $t_0$  at layer  $\ell$ :

$$180 \quad \mathbf{h}_v^{(\ell)} = \sigma \left( W_{t_0, \text{self}}^{(\ell)} \mathbf{h}_v^{(\ell-1)} + \sum_{t \in \mathcal{T}} W_{t \rightarrow t_0}^{(\ell)} \frac{1}{|N_t(v)|} \sum_{u \in N_t(v)} \mathbf{h}_u^{(\ell-1)} + \mathbf{b}_{t_0}^{(\ell)} \right).$$

181  
 182

183 Our decomposition naturally extends:  
 184

$$185 \quad \mathbf{C}_{\cdot \rightarrow v}^{(\ell+1)} = D_v^{(\ell)} \left( W_{t_0, \text{self}}^{(\ell)} \mathbf{C}_{\cdot \rightarrow v}^{(\ell)} + \sum_{t \in \mathcal{T}} W_{t \rightarrow t_0}^{(\ell)} \frac{1}{|N_t(v)|} \sum_{u \in N_t(v)} \mathbf{C}_{\cdot \rightarrow u}^{(\ell)} + \mathbf{b}_{t_0}^{(\ell)} \right). \quad (2)$$

186  
 187

188 Because contributions are partitioned by node type, we obtain explanations such as “merchant fea-  
 189 tures” vs. “account features,” reflecting the heterogeneous semantics. For link prediction, HinSAGE  
 190 produces edge embeddings  $\psi(\mathbf{h}_u^{(L)}, \mathbf{h}_v^{(L)})$ , commonly via Hadamard product or concatenation, fol-  
 191 lowed by a linear classifier. Since these operators are linear in  $\mathbf{h}_u^{(L)}$  and  $\mathbf{h}_v^{(L)}$ , contributions extend  
 192 seamlessly. For example, with Hadamard product:  
 193

$$194 \quad \ell_{uv} = \mathbf{w}^\top (\mathbf{h}_u^{(L)} \odot \mathbf{h}_v^{(L)}) + c,$$

195

196 the contribution of feature  $p$  of node  $w$  is obtained by combining node-level contributions with  
 197  $\text{diag}(\mathbf{w}) \mathbf{h}_v^{(L)}$  or  $\text{diag}(\mathbf{w}) \mathbf{h}_u^{(L)}$ , depending on whether  $w$  lies in the neighborhood of  $u$  or  $v$ . This  
 198 yields edge-level decompositions that directly attribute predicted links to original features of source  
 199 and destination neighborhoods. Because HinSAGE uses random neighborhood sampling, expla-  
 200 nations are conditional on the computation graph. Averaging across samples produces expected  
 201 contributions, while a single sample yields instance-specific explanations.  
 202

203 By expressing GNN layers as masked linear operators and propagating contributions in parallel to  
 204 the forward pass, our framework provides exact, activation-conditioned decompositions of embed-  
 205 dings into original features. The GCN case highlights hop- and neighbor-wise propagation, while  
 206 HinSAGE showcases type-aware, edge-level sampling in heterogeneous graphs. Together, these ex-  
 207 amples demonstrate our method’s generalizability across major GNN architectures, enabling prin-  
 208 cipled, feature-level interpretability of embeddings and predictions.  
 209

## 210 3 QUALITATIVE EXPERIMENTS

### 211 3.1 DATASETS AND EXPERIMENTAL SETUP

212 To illustrate the proposed decomposition framework, we consider two datasets using two GNN  
 213 architectures: the Cora citation network (Sen et al., 2008) using GCN and the MovieLens dataset  
 214 (Harper & Konstan, 2015) using HinSAGE. Further details are provided in the Appendix. All models  
 215 are implemented using the StellarGraph library (Data61, 2018).

216 3.2 RESULTS  
217

218 **Cora (GCN case study).** We compare an XGBoost model (Chen & Guestrin, 2016) trained on raw  
219 1,433 BoW features against an XGBoost model trained on only the 16 GCN embeddings from the  
220 last hidden GCN layer. Using embeddings yields a performance lift, improving accuracy from 0.57  
221 to 0.76 and weighted F1 score from 0.56 to 0.75. Since the embeddings are predictive features for  
222 downstream tasks, explaining the embeddings is necessary to understand the information captured  
223 by the GCN.

224 We decompose each embedding back to the original features by expanding the actual passing with  
225 the trained weights and ReLU gates. For a target node  $v$ , source node  $w$ , and feature index  $p$ , the  
226 contribution vector  $[\mathbf{C}_{w \rightarrow v}^{(2)}]_{p,:}$  can be calculated using the equation 1, where  $D^{(0)}$  and  $D^{(1)}$  denote  
227 the diagonal ReLU gating at layer 1 and 2. This makes the two-hop paths explicit and preserves  
228 the exact trained computation (e.g., bias flow and ReLU gates). In all feature-attribution summaries  
229 below, we exclude the bias term so that values reflect word contributions only. To separate whether  
230 an embedding’s influence originates from the node itself or from neighbors, we decompose the  
231 renormalized adjacency into diagonal and off-diagonal parts,

$$232 \tilde{A} = \tilde{A}_{\text{self}} + \tilde{A}_{\text{nbr}}, \quad (\tilde{A}_{\text{self}})_{uw} = \begin{cases} \tilde{A}_{uu}, & u = w, \\ 233 0, & u \neq w. \end{cases}.$$

234 Let  $[\mathbf{C}_{w \rightarrow v}^{(2)}]_{p,:}$  denote the layer-2 contribution vector from feature  $p$  of source node  $w$  to the em-  
235 bedding of target node  $v$ . We obtain *self-origin* and *neighbor-origin* contributions by replacing  
236 the factor  $\tilde{A}_{uw}$  in that expansion with  $(\tilde{A}_{\text{self}})_{uw}$  and  $(\tilde{A}_{\text{nbr}})_{uw}$ , respectively:  $[\mathbf{C}_{\text{self}, w \rightarrow v}^{(2)}]_{p,:} :=$   
237  $[\mathbf{C}_{w \rightarrow v}^{(2)}]_{p,:} \Big|_{\tilde{A}_{uw} \leftarrow (\tilde{A}_{\text{self}})_{uw}}$ , and  $[\mathbf{C}_{\text{nbr}, w \rightarrow v}^{(2)}]_{p,:} :=$   
238  $[\mathbf{C}_{w \rightarrow v}^{(2)}]_{p,:} \Big|_{\tilde{A}_{uw} \leftarrow (\tilde{A}_{\text{nbr}})_{uw}}$ . Since embeddings  
239 can exhibit correlation, we optionally apply a PCA-based projection to visualize attribution  
240 patterns in an orthogonal basis (see Section A.2). This step is intended for interpretability and vis-  
241 ualization. Let  $V \in \mathbb{R}^{d \times r}$  be the top  $r$  PCA loadings (columns orthonormal) fit once on  $\mathbf{H}^{(2)}$ . We  
242 rotate each contribution vector over the embedding axis and sum the first  $r$  principal components:  
243

$$244 \tilde{\mathbf{C}}_{\star, w \rightarrow v}^{(2)}[p, 1:r] = \mathbf{C}_{\star, w \rightarrow v}^{(2)}[p, :] V, \quad [\mathbf{s}_{\star}^{\text{PCA}}(v)]_p = \sum_{w \in \mathcal{V}} \sum_{c=1}^r \tilde{\mathbf{C}}_{\star, w \rightarrow v}^{(2)}[p, c], \quad \star \in \{\text{self, nbr}\},$$

245 where  $d = 16$  and  $r = 5$  in this example. Stacking rows over  $v$  yields matrices

$$246 S_{\text{self}}, S_{\text{nbr}} \in \mathbb{R}^{N \times F},$$

247 whose  $v$ -th rows are the correlation-adjusted word attributions  $\mathbf{s}_{\text{self}}^{\text{PCA}}(v)^\top$  and  $\mathbf{s}_{\text{nbr}}^{\text{PCA}}(v)^\top$ .

248 To visualize contributions, we apply t-SNE (Maaten & Hinton, 2008) to reduce  $S_{\text{self}}$  and  $S_{\text{nbr}}$  (1,433  
249 words) to two dimensions. Figure 1 shows contributions obtained by decomposing GCN embed-  
250 dings, comparing self-node and neighbor-node representations. Our intention is not to claim strong  
251 separation based solely on t-SNE, but rather to provide an intuitive illustration of contribution pat-  
252 terns. Incorporating neighborhood information appears to influence embedding structure, which  
253 aligns with observed gains in recall performance (e.g., *Reinforcement Learning*: 0.44 to 0.72, *The-  
254 ory*: 0.18 to 0.56, *Rule Learning*: 0.37 to 0.64). Figure 3 in the appendix reports full performance  
255 results across all categories. Because this analysis is conducted at the feature-contribution level, it  
256 offers transparency into what each embedding learns individually by grouping features with sim-  
257 ilar contribution behaviors, helping interpret the role of neighborhood aggregation in shaping model  
258 predictions.

259 **MovieLens (HinSAGE case study).** We then interpret the embeddings generated by the Hin-  
260 SAGE model. Following the approach used for the GCN example, we treat these embeddings as  
261 additional features and compare two XGBoost models: one using only user and movie attributes,  
262 and another incorporating both raw attributes and embeddings. Incorporating embeddings improves  
263 predictive performance across key metrics: MSE decreases from 1.12 to 0.95, MAE from 0.86 to  
264 0.78, and  $R^2$  nearly doubles from 0.11 to 0.24. Feature importance from the XGBoost regressor  
265 (total gain) highlights the predictive value of embeddings, with only one raw user attribute (scaled  
266 age) appearing among the top 20 features. These results underscore the necessity of explaining

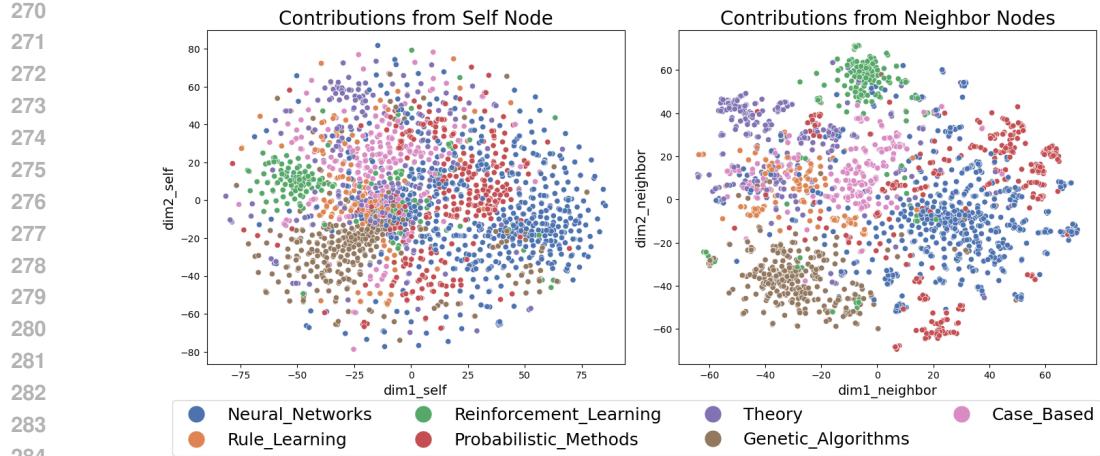

Figure 1: t-SNE visualization of feature contributions from decomposed GCN embeddings. The left panel shows contributions from self nodes, while the right panel shows contributions from neighbor nodes. Notably, the neighbor node contributions exhibit clearer separation across categories, indicating their stronger role in capturing class-discriminative information.

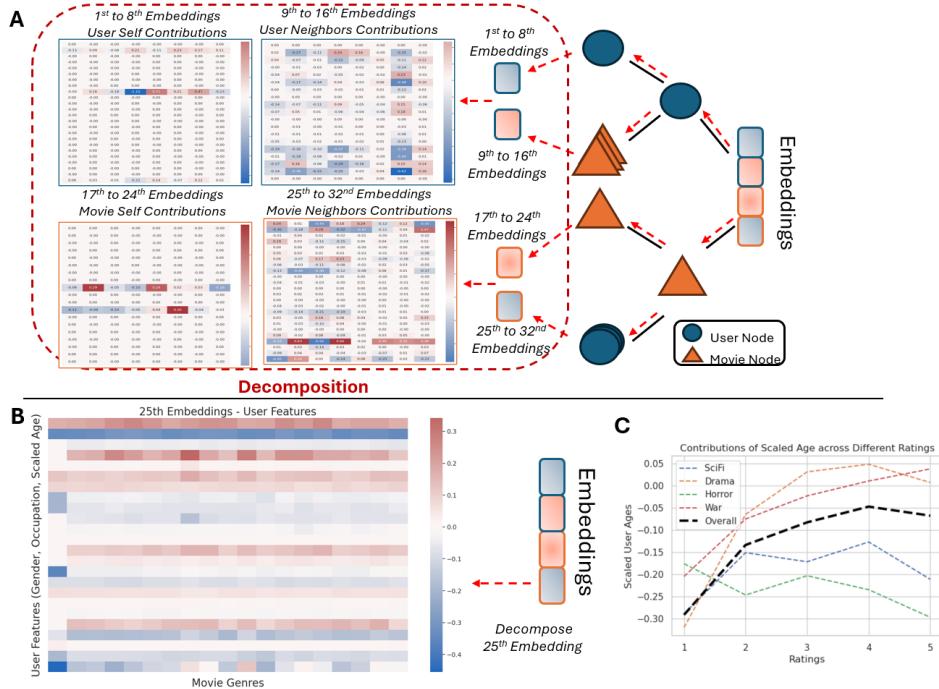

Figure 2: A. Decomposition of user–movie HinSAGE embeddings into self-contributions and neighbor-contributions for both users and movies, illustrating how individual components construct the learned representation. B. Analysis of the 25<sup>th</sup> embedding dimension by aggregating contributions across user groups and comparing them across different movie genres, highlighting systematic differences in representation structure. C. Contributions of the user attribute *scaled age* across different rating levels, aggregated by movie genres.

embeddings, as they encode highly informative signals. Figure 4 in the appendix provides the full comparisons between two XGB models across different rating levels.

To this end, we decompose the learned embeddings using the equation 2. Figure 2A illustrates this process for a single user–movie pair. Then, we leverage learned weights to map each embedding back to its contributing features. The decomposition yields four contribution matrices corresponding to: (a) user self-node (dimensions 1–8), (b) user’s neighboring movie nodes (9–16), (c) movie self-node (17–24), and (d) movie’s neighboring user nodes (25–32). For example, the unnormalized value of the 17th embedding dimension is  $-0.18$ , with the movie attributes *drama* and *horror* contributing  $-0.06$  and  $-0.12$ , respectively, while other attributes have negligible impact. Beyond single-pair analysis, we examine the most influential embedding (25<sup>th</sup>, with an importance score of 0.18 using the “total\_gain” metric) by aggregating contributions across multiple pairs. As shown in Figure 2A, this embedding primarily captures information from neighboring users of the target movie, reflecting collaborative signals. Figure 2B compares aggregated contributions across user groups and movie genres, revealing systematic differences in representation structure (e.g.,  $-0.21$  for *animation* vs.  $0.09$  for *documentary*). Finally, we analyze the role of a specific user attribute—*scaled age*—across rating levels and genres. Figure 2C shows that *war* and *drama* genres exhibit trends aligned with the overall population (increasing with rating), whereas *sci-fi* and *horror* display the opposite pattern, with younger users tending to assign higher ratings. Contribution values amplify these differences: *war* and *drama* show near-zero contributions, while *sci-fi* and *horror* exhibit strongly negative contributions, indicating their distinct influence on embedding formation.

Appendix A.4 provides additional results. Figure 5 shows average scaled-age contributions to the 25<sup>th</sup> embedding; Figure 6 examines the *job=artist* subpopulation across rating levels. High-contribution genres trend upward with rating, whereas low-contribution genres are essentially flat. In addition, we analyze the 11<sup>th</sup> embedding—constructed from users’ movie-neighbor signals—with a focus on the *War* genre (Figure 7); compared to contribution results from 25<sup>th</sup> embedding dimension, the contribution curves for the 11<sup>th</sup> embedding cluster more tightly, indicating that differences among features are subtle and not strongly discriminative for this genre. These findings demonstrate that our proposed attribution-based decomposition provides a step toward improving interpretability of graph-based embeddings and offers insights into how heterogeneous relational signals influence predictive performance.

## 4 QUANTITATIVE EXPERIMENTS

### 4.1 DATASETS AND EXPERIMENTAL SETUP

We conducted quantitative experiments to compare our explanation method against a suite of baselines, including GOAt (Lu et al., 2024), GNN-LRP (Schnake et al., 2021), Integrated Gradients (IG) (Sundararajan et al., 2017b), GradCAM (Pope et al., 2019), LIME (Ribeiro et al., 2016), and a Random baseline. All methods operate on the same GCN backbone under identical training configurations to ensure fairness. Specifically, the backbone consists of 2 graph convolutional layers with ReLU activation, followed by a linear output layer. Each hidden layer has 64 dimensions, and training is performed for 500 epochs using the Adam optimizer with a learning rate of 0.05 and weight decay of  $5 \times 10^{-4}$ . A dropout rate of 0.5 is applied to mitigate overfitting.

**Evaluation Metrics.** We adopt faithfulness-based metrics widely used in interpretability research and adapted for graph settings (Yuan et al., 2023). Let  $f(\cdot)$  denote the GNN classifier that outputs the predicted probability for the ground-truth class,  $x$  the original input feature vector, and  $\phi(x)$  its feature-attribution vector. We define  $x_k^+$  as the input where only the top- $k\%$  most important features (according to  $\phi(x)$ ) are retained, and  $x_k^-$  as the input where these top- $k\%$  features are masked. *Fidelity<sub>−</sub>* measures signal preservation when retaining top- $k\%$  features, computed as  $\mathbb{E}[f(x_k^+) - f(x)]$ , while *Fidelity<sub>+</sub>* captures the effect of removing these features, computed as  $\mathbb{E}[f(x_k^-) - f(x)]$ . To assess stability, we employ Robustness to Feature Noise, where Gaussian noise  $\epsilon \sim \mathcal{N}(0, 1)$  is added to obtain  $x' = x + 0.05 * \sigma * \epsilon$ , and robustness is quantified as  $1 - \|\phi(x) - \phi(x')\| / \|\phi(x)\|$ , where  $\sigma$  denotes the standard deviation of the original features. Higher values indicate explanations that are both faithful and stable under perturbations.

**Datasets.** We evaluate on five widely used benchmark datasets for node classification: Amazon-Computers (D1) and Amazon-Photo (D2) from Shchur et al. (2018), CiteSeer (D3), PubMed (D4) and Cora (D5) from Yang et al. (2016). These datasets span diverse graph structures and feature

378  
 379 Table 2: Comparison of Fidelity<sub>+</sub> and Fidelity<sub>-</sub> scores for GNN-LRP, GOAT, IG, GradCAM,  
 380 LIME, Random, and our self+2hop method across Amazon-Computers (D1), Amazon-Photo (D2),  
 381 Citeseer (D3), PubMed (D4), and Cora (D5). Values are averaged over 100 random nodes, using  
 382  $k = 5\%$  of features masked.

394  
 395 distributions, making them standard for GNN explainability research. Dataset statistics (nodes,  
 396 edges, feature dimensions, and class distributions) are summarized in Table 4.  
 397

## 398 4.2 RESULTS

400 Table 2 reports Fidelity<sub>+</sub> and Fidelity<sub>-</sub> scores across all datasets. Fidelity<sub>+</sub> measures the difference  
 401 in prediction when the top-5% important features are removed compared to the original input.  
 402 Larger values indicate that the retained features capture most of the predictive signal, while Fidelity<sub>-</sub>  
 403 measures the difference when only the top-5% important features are kept. Here, smaller values are  
 404 better, as they indicate that masking less relevant features does not significantly distort predictions.  
 405 In summary, our method achieves state-of-the-art Fidelity<sub>+</sub>, closely matching or surpassing GOAt  
 406 on most of benchmarks and outperforming gradient-based and perturbation-based methods, demon-  
 407 strating that the proposed decomposition effectively identifies features critical for preserving model  
 408 confidence. Moreover, our method achieved near-zero Fidelity<sub>-</sub> values, confirming that the decom-  
 409 position produces clean and stable feature rankings.

410 Robustness results, summarized in Table 5 (Appendix), show that our method outperforms IG, GNN-  
 411 LRP, and LIME. The slightly lower robustness is expected because the proposed method operates  
 412 directly in the input feature space, where additive noise proportionally perturbs the importance mag-  
 413 nitudes. Nevertheless, robustness values remain high (0.78–0.98), demonstrating that the method  
 414 is relatively stable. Finally, Table 6 (Appendix) compares computational efficiency. Our method  
 415 achieves a favorable trade-off between efficiency and faithfulness.

416 We also investigate feature signal recovery under feature noise by augmenting Cora’s 1,433 features  
 417 with 287 Bernoulli noise columns ( $p=0.013$ ), comparing our method against established baselines. A  
 418 2-layer GCN (details in Section A.5) is trained, and 100 test nodes are sampled. Each explainer ranks  
 419 features; we measure the number of noisy features among the Top-10 and report runtime statistics.  
 420 Results (Appendix 8) show our method consistently selects fewer noisy features, with PCA-based  
 421 aggregation offering slight gains over averaging—indicating improved stability and signal recovery.

## 422 5 DISCUSSION

### 423 5.1 LIMITATIONS AND SCOPE

424 Our decomposition framework attributes embedding values to input features by propagating contrib-  
 425 utions through the network’s computational graph, assuming access to model internals (parame-  
 426 ters, intermediate activations, and stored normalization statistics) and achieving exactness only for  
 427 specific activation and normalization classes. For linear transformations and piecewise-linear ac-  
 428 tivations such as ReLU (Nair & Hinton, 2010) and LeakyReLU (Maas et al., 2013), contributions  
 429 admit closed-form propagation via sign/magnitude masks or slope-based scaling. Monotone acti-  
 430

432 variations with tractable inverses (e.g., ELU (Clevert et al., 2016), SELU (Klambauer et al., 2017),  
 433 Softplus (Nair & Hinton, 2010)) are handled by exact inversion when numerically stable, or by local  
 434 linearization using their derivatives for saturating nonlinearities such as Sigmoid and Tanh, which  
 435 are invertible in principle, we employ clamping or derivative-weighted masks to mitigate numerical  
 436 instability near saturation. Modern smooth activations (GELU (Hendrycks & Gimpel, 2017),  
 437 Swish/SiLU (Ramachandran et al., 2017), Mish (Misra, 2019)) lack simple closed-form inverses  
 438 and can be non-monotonic. However, Hendrycks & Gimpel (2017) provides the approximated form  
 439 of GELU with  $f(x) = 0.5x \left( 1 + \tanh \left[ \frac{\sqrt{2}}{\pi} (x + 0.044715x^3) \right] \right)$ , which can be inverted using a  
 440 branch-aware Newton–Raphson method on  $g(x) = f(x) - y$  with close-form  $f'(x)$ . Alternatively,  
 441 DeepLIFT (Shrikumar et al., 2017) or LRP (Bach et al., 2015) provide principled propagation with-  
 442 out explicit inversion for non-monotonic cases. Normalization layers exhibit analogous behavior:  
 443 BatchNorm (Ioffe & Szegedy, 2015) is invertible at inference given stored statistics as discussed  
 444 in Lu et al. (2024), while LayerNorm (Ba et al., 2016) depends on per-sample moments and is  
 445 treated via local linearization. Pooling and attention are decomposed by distributing relevance pro-  
 446 portionally to aggregation weights or attention scores, preserving interpretability in graph-based  
 447 architectures.

448 The proposed approach assumes access to model internals—such as weights, activations, and nor-  
 449 malization statistics. In black-box settings (e.g., API-based inference), these details are unavailable,  
 450 making exact decomposition infeasible. This is not unique to our approach: widely used popula-  
 451 tion/global explainers require access to model internals (Ying et al., 2019; Baldassarre & Azizpour,  
 452 2019; Luo et al., 2020; Lu et al., 2024). If internal access is restricted, alternative approaches like  
 453 model-agnostic methods, perturbation-based sensitivity analysis, or surrogate modeling can approx-  
 454 imate interpretability, albeit with reduced faithfulness.

455 Above, we used PCA as a post-hoc visualization tool to aggregate the contribution matrix in order  
 456 to show overall patterns across interpretations. While PCA can be effective for summarizing high-  
 457 dimensional data, it introduces an additional layer of abstraction. However, we note that PCA is not  
 458 part of the explanation mechanism itself—the raw contribution matrix remains available for direct  
 459 analysis. Alternative aggregation strategies that preserve interpretability are important future work,  
 460 such as TCAV introduced by Kim et al. (2018), which aligns latent directions with human-defined  
 461 concepts, or disentangled representation learning (Piaggesi et al., 2025), which aims to produce  
 462 dimensions with clearer semantic meaning.

## 463 5.2 FUTURE WORK

465 **Graph Attention Networks (GAT).** As a future direction, we aim to extend our path-based de-  
 466 composition framework to attention-based architectures such as GAT, which often outperform non-  
 467 attention GNNs (Veličković et al., 2018). While we provide a detailed decomposition for a simplified  
 468 two-layer GAT in Appendix A.6, this is only a preliminary step. Generalizing to deeper GATs, het-  
 469 erogeneous attention mechanisms, and residual connections remains an open challenge that we plan  
 470 to explore in future work.

471 **Graph Transformer (GT).** Recent advances in Graph Transformers (Yun et al., 2019) pose a  
 472 challenge to our path-based formulation. By replacing sparse neighborhoods with fully-connected  
 473 attention, GTs allow each node to attend to all others, which eliminates the locality-based prop-  
 474 agation structure that our method exploits. To address this challenge, we need to determine how  
 475 to define paths through a dense attention mechanism without facing combinatorial explosion. One  
 476 promising direction is to track only the most influential connections, potentially through iterative  
 477 pruning or hierarchical clustering of attention patterns. Second, GTs commonly use positional en-  
 478 codings like Laplacian eigenvectors or shortest path distances capture structure, but these encodings  
 479 are processed jointly with node features through the same attention mechanism. Separating the po-  
 480 sitional and node-feature contributions is an open problem, but necessary to capture the impact of  
 481 the node features on the network’s decision process.

482 **Uncertainty Quantification.** Beyond extending the framework to other convolutional architec-  
 483 tures, an important research direction is to incorporate confidence measures into explanations. Cur-  
 484 rent attribution methods—including ours—assume deterministic faithfulness within activation re-  
 485 gions, but do not quantify uncertainty under distribution shifts or adversarial perturbations. Fu-

ture work could explore probabilistic decomposition techniques to estimate explanation reliability, enabling practitioners to assess whether an attribution remains trustworthy when the input graph deviates from training distribution.

## 6 CONCLUSION

This paper introduced a feature-wise decomposition framework for interpreting graph neural network embeddings. By reformulating GNN layers as linear contribution operators, our approach provides explicit attributions across both self and neighbor pathways, while a PCA-based aggregation strategy mitigates correlation bias among embedding dimensions. Experiments on homogeneous (Cora) and heterogeneous (MovieLens) benchmarks demonstrate that our method delivers fine-grained, semantically aligned explanations of predictive embeddings. These results underscore the value of embedding decomposition for revealing how relational signals shape learned representations, thereby advancing transparency and accountability in GNN-driven decision-making. Looking ahead, this work opens promising directions for extending the framework to deeper architectures, temporal or dynamic graphs, and high-stakes domains where interpretability is critical.

## 723 A APPENDIX

### 725 A.1 NOTATION

727 Symbol	728 Definition
729 $G = (\mathcal{V}, \mathcal{E})$	730 Input graph with node set $\mathcal{V}$ and edge set $\mathcal{E}$
731 $\mathbf{x}_v \in \mathbb{R}^{F_0}$	732 Input feature vector of node $v$
733 $X \in \mathbb{R}^{ \mathcal{V}  \times F_0}$	734 Matrix of all input features
735 $\mathbf{h}_v^{(\ell)} \in \mathbb{R}^{F_\ell}$	736 Embedding of node $v$ at layer $\ell$
736 $W^{(\ell)}$	737 Learnable weight matrix at layer $\ell$
737 $W_r^{(\ell)}$	738 Relation/type-specific weight matrix
738 $\mathbf{b}^{(\ell)}$	739 Bias vector at layer $\ell$
739 $\sigma$	740 Nonlinear activation (e.g., ReLU)
740 $D_v^{(\ell)}$	741 Diagonal mask from activation of node $v$ at layer $\ell$
741 $N_r(v)$	742 Neighbors of $v$ under relation/type $r$
742 $\tilde{A}$	743 Normalized adjacency matrix used in GCN
743 $\mathbf{e}_p$	744 $p$ -th standard basis vector in $\mathbb{R}^{F_0}$ , 745 i.e., a column vector with 1 in position $p$ and 0 elsewhere
744 $\mathbf{C}_{w \rightarrow v}^{(\ell)}$	746 Contribution matrix from features of node $w$ to embedding of node $v$ at layer $\ell$

747 Table 3: Notation used in the Methods section.

### 748 A.2 PCA-BASED CONTRIBUTION AGGREGATION

749 A central difficulty in aggregating feature contributions across embeddings is that the learned em-  
 750 beddings are often correlated. Directly summing raw contribution vectors may therefore over-count  
 751 redundant information. One possible remedy is whitening, which rescales contributions by the  
 752 inverse square root of the embedding covariance matrix (Zuber & Strimmer, 2011). However, in prac-  
 753 tice the covariance matrix  $\Sigma_h$  may be ill-conditioned, and computing  $\Sigma_h^{-1/2}$  can lead to numerical  
 754 instability due to very small eigenvalues.

755 We instead adopt a principal component analysis (PCA) approach (Jolliffe & Cadima, 2016). Let  
 $\Sigma_h = U \Lambda U^\top$  denote the eigen decomposition of the embedding covariance, with eigenvectors  $U$

756 and eigenvalues  $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_{F_L})$ . We transform each contribution vector  $\mathbf{c}_{w,p \rightarrow v} \in \mathbb{R}^{F_L}$   
 757 into the orthogonal PCA basis such that  $\hat{\mathbf{c}}_{w,p \rightarrow v} = \mathbf{c}_{w,p \rightarrow v} U$ . The coordinates of  $\hat{\mathbf{c}}_{w,p \rightarrow v}$  now  
 758 represent the effect of feature  $p$  of node  $w$  on independent directions of variation in the embedding  
 759 space. A simple PCA-based importance score is then

$$s_{w,p \rightarrow v}^{\text{PCA}} = \|\hat{\mathbf{c}}_{w,p \rightarrow v}\|_2,$$

762 which measures the overall magnitude of influence across decorrelated components.

763 Alternatively, one can weight contributions by the fraction of variance explained by its principal  
 764 component:

$$s_{w,p \rightarrow v}^{\text{PCA-var}} = \left( \sum_{k=1}^{F_L} \frac{\lambda_k}{\sum_j \lambda_j} (\hat{\mathbf{c}}_{w,p \rightarrow v}[k])^2 \right)^{1/2}.$$

769 This PCA-based approach avoids the instability of inverting  $\Sigma_h$  while still capturing feature con-  
 770 tributions along independent directions of variation in the embedding space. In practice, we often  
 771 truncate to the top  $K$  principal components, which both reduces noise and highlights contributions  
 772 to dominant modes of variation.

### 773 A.3 DATASET DESCRIPTIONS AND EXPERIMENTAL SETUP

774 **Cora (GCN case study).** The Cora citation network (Sen et al., 2008) consists of 2,708 scientific  
 775 publications categorized into seven research areas, connected by 5,429 citation links. Each node  
 776 represents a paper, and its feature vector is a bag-of-words (BoW) representation over 1,433 unique  
 777 terms from the papers. The prediction task is node classification: given the citation graph and node  
 778 features, predict the research category of each paper. We adopt the standard train/validation split  
 779 from Kipf & Welling (2017), with the remaining nodes reserved for testing. This dataset provides  
 780 a benchmark for evaluating our method in a transductive, homogeneous, single-type graph setting,  
 781 where GCN serves as a natural baseline. For the experimental setup, we train a two-layer GCN,  
 782 where each layer outputs 16 hidden dimensions, followed by ReLU activation and dropout with a  
 783 rate of 0.5. The final layer is a softmax classifier over seven publication categories. Training is  
 784 performed using the Adam optimizer with a learning rate of 0.01, minimizing the cross-entropy loss  
 785 on labeled nodes. We use 140 nodes for training, 500 for validation, and 2,068 for testing. Early  
 786 stopping is applied based on validation accuracy with a patience of 10 epochs.

787 **MovieLens (HinSAGE case study).** The MovieLens dataset (Harper & Konstan, 2015) comprises  
 788 user–movie interactions represented as a bipartite heterogeneous graph. We use the 100K subset,  
 789 which contains 100,000 ratings from 943 users on 1,682 movies. Nodes correspond to users and  
 790 movies, while edges denote rating interactions. Node features include auxiliary attributes such as  
 791 movie genres and user profiles. Each edge is associated with an integer rating in the range [1,5].  
 792 We formulate the task as supervised link-attribute regression: given a user node, a movie node, and  
 793 their attributes, the model predicts the rating on the corresponding edge. This setting evaluates our  
 794 framework under an inductive, heterogeneous, edge-level prediction scenario. Our model adopts a  
 795 one-layer HinSAGE architecture as suggested in Zhang & Chen (2020) with a hidden dimension of  
 796 16 and a mean aggregator. For each target node, the model samples neighborhoods of size 200 to  
 797 compute node embeddings. Edge embeddings are constructed by concatenating the embeddings of  
 798 user–movie pairs and passing them through a dense layer of size 16 with a linear activation, followed  
 799 by a single linear output unit to produce a continuous rating prediction. The model is optimized using  
 800 Adam with a learning rate of 0.01 and trained with mean squared error (MSE) as the objective. We  
 801 allocate 60,000 edges for training, 10,000 for validation, and 30,000 for testing. Early stopping is  
 802 applied based on validation mean absolute error (MAE) with a patience of 5 epochs.

### 804 A.4 ADDITIONAL RESULTS

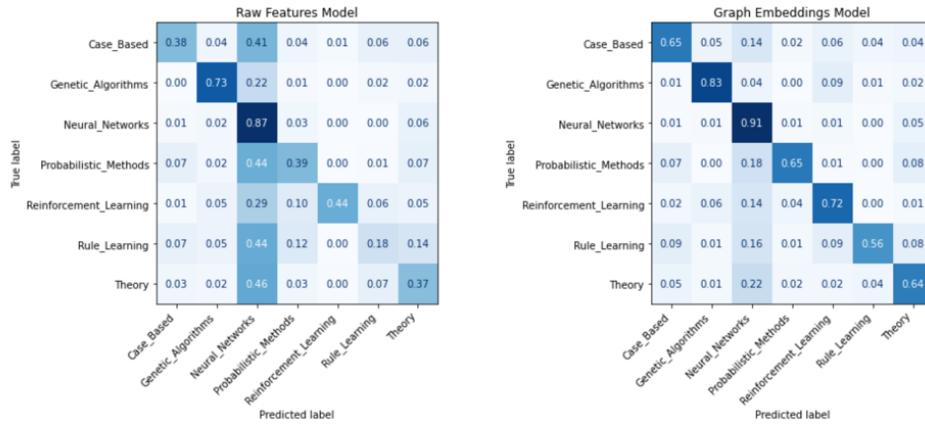

Figure 3: Confusion matrices of XGBoost trained with (a) raw bag-of-words features and (b) GCN-derived embeddings. The GCN embeddings produce a more diagonally dominant pattern and suppress structured off-diagonal blocks, indicating improved class separability and reduced systematic confusion among semantically related classes. Labels are ordered consistently across panels.

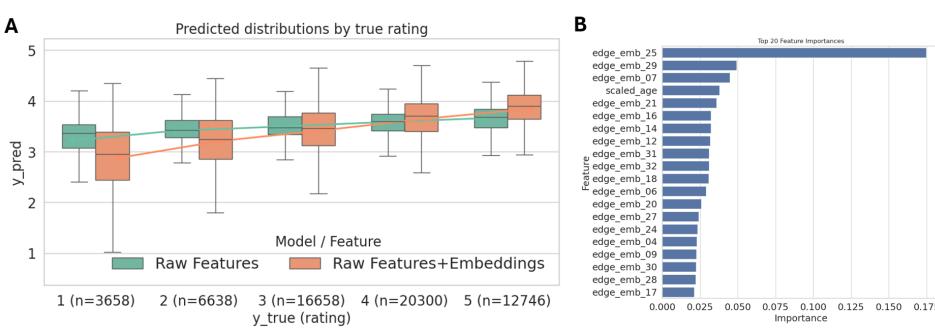

Figure 4: A. Model performance comparison for XGBoost regression on the MovieLens dataset using either raw features or raw + HinSAGE embeddings. Boxplots show predicted rating distributions (y-axis) grouped by true rating levels (x-axis). Quantitatively, adding embeddings decreases mean squared error (MSE) and mean absolute error (MAE) while increasing  $R^2$ , demonstrating that learned representations capture latent structure beyond raw features. B. Feature importance (measured by total gain) from the XGBoost regression model. Embedding dimensions dominate the top-ranked features (e.g., edge\_emb\_25, edge\_emb\_29, edge\_emb\_07), indicating that learned graph-based representations contribute more to predictive performance than raw user attributes.

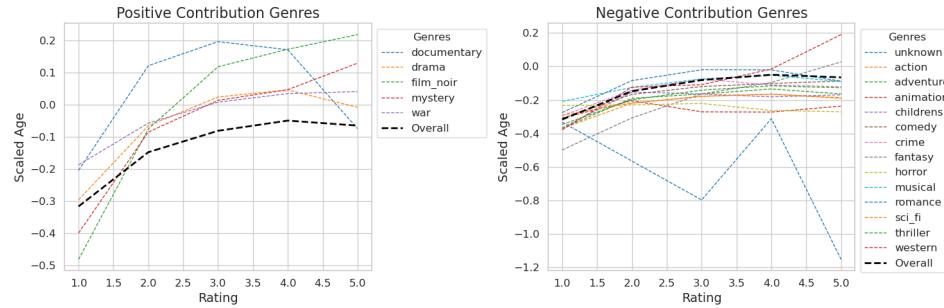

864

865

866

867

868

877

878

879 Figure 5: Average contributions of the scaled age attribute to the 25<sup>th</sup> graph embedding across  
 880 rating levels (x-axis) and aggregated by movie genres. The left panel shows genres where age  
 881 exhibits positive contributions (e.g., documentary, drama, film noir, mystery, war), while the right  
 882 panel shows genres with negative contributions (e.g., action, animation, comedy, horror). Each curve  
 883 represents the marginal effect of scaled age on the model’s output for a given genre, averaged over  
 884 users and items. Positive-contribution genres generally show an increasing trend with rating level,  
 885 indicating that older users are associated with higher ratings for these genres. Conversely, negative-  
 886 contribution genres seem to exhibit decreasing or flat trends, suggesting that younger users tend to  
 887 give higher ratings in these categories. The overall trend (black dashed line) summarizes the global  
 888 effect across all genres.

889

890

891

892

897

907

908

909 Figure 6: Average contributions of the Artist job feature to the 25<sup>th</sup> graph embedding across rating  
 910 levels (x-axis), aggregated by movie genres. The left panel shows genres with high contribution  
 911 ( $\geq 0.2$ ), including animation, children’s, crime, documentary, film noir, musical, and mystery. The  
 912 right panel shows genres with low contribution ( $< 0.2$ ), such as action, adventure, comedy, drama,  
 913 horror, and others. High-contribution genres tend to exhibit stronger positive sensitivity to higher  
 914 ratings, whereas low-contribution genres remain relatively flat, indicating limited influence of the  
 915 Artist feature in those categories. The black dashed line denotes the overall trend across all genres.

Figure 7: A. Analysis of the 11<sup>th</sup> embedding dimension, showing aggregated contributions across movie genres (rows) and user attributes (columns). Each cell represents the marginal effect of a user feature on this embedding dimension for a given genre, with darker shades indicating stronger negative contributions. User attributes include gender, occupation categories, and scaled\_age, which is treated as a binary feature here (results correspond to cases where scaled\_age > 0). Analysis of the 11<sup>th</sup> embedding dimension, showing aggregated contributions across movie genres (rows) and user attributes (columns). Each cell represents the marginal effect of a user feature on this embedding dimension for a given genre, with darker shades indicating stronger negative contributions. User attributes include gender, occupation categories, and scaled\_age, which is treated as a binary feature here (results correspond to cases where scaled\_age > 0). B. Visualization of average user feature contributions for the war genre across rating levels (x-axis). The left panel shows features with high aggregate contribution ( $\geq 0.2$ ), primarily occupational attributes (e.g., administrator, educator, engineer, scientist) and scaled\_age (binary,  $> 0$ ). The right panel shows features with low aggregate contribution ( $< 0.2$ ), including gender and less influential occupations. Each curve represents the marginal effect of a user feature on predicted ratings for war movies, averaged across users and items. The curves cluster closely, indicating that differences among these features are subtle and not strongly discriminative for this genre.

972 A.5 COMPARATIVE EVALUATION ON NOISY CORA  
973  
974  
975  
976  
9771001 Figure 8: Frequency distributions of noisy features across different explanation methods using a  
1002 GCN model on the Cora dataset.  
10031004 We compare our decomposition based approach with established baselines: GOAt (Lu et al., 2024),  
1005 GNNExplainer (Ying et al., 2019), Integrated Gradients (Sundararajan et al., 2017a), LIME (Ribeiro  
1006 et al., 2016), GraphLIME (Huang et al., 2022), and a Random explainer. Our method inverts layer-  
1007 wise embeddings back to raw features and aggregates contributions either by simple averaging  
1008 across embedding dimensions or via a PCA based decorrelation. We evaluate how effectively com-  
1009 peting explanation methods suppress uninformative (noise) node features on the Cora dataset. Fol-  
1010 lowing prior work (Huang et al., 2022; Duval & Malliaros, 2021), we augment the original 1,433  
1011 bag of words features with 287 additional Bernoulli ( $p=0.013$ ) noise columns, which have a similar  
1012 distribution as existing features. We train a 2 layer GCN with the same settings as in Section 3.1.  
1013 We sample 100 test nodes; each explainer produces a feature importance vector, and we count how  
1014 many of the Top 10 ranked features are the added noisy features. We report the mean and standard  
1015 deviation of the runtime per node across these 100 nodes.1016 Figure 8 shows that, across the sampled nodes, our method selects the fewest noisy features in  
1017 general, indicating higher attribution precision. For the PCA-based aggregation, using more principal  
1018 components (e.g., 10 PCs) seem to achieve a small but consistent gain over fewer PCs (e.g., 2 PCs)  
1019 and over simple averaging—suggesting that PCA-based aggregation helps to improve stability and  
1020 signal recovery. Overall, the decomposition framework attains a favorable fidelity–efficiency trade  
1021 off compared to existing baselines.

1080 A.6 DECOMPOSITION FOR TWO-LAYER GAT  
10811082 For layer  $\ell$  and head  $k$ , with input features  $\mathbf{h}_j^{(\ell)} \in \mathbb{R}^{F_\ell}$ ,

1083 
$$\mathbf{z}_j^{(\ell,k)} = \mathbf{W}^{(\ell,k)} \mathbf{h}_j^{(\ell)} \in \mathbb{R}^{F'_\ell},$$

1084 
$$e_{ij}^{(\ell,k)} = \text{LeakyReLU}\left(\mathbf{a}^{(\ell,k)\top} [\mathbf{z}_i^{(\ell,k)} \parallel \mathbf{z}_j^{(\ell,k)}]\right),$$

1085 
$$\alpha_{ij}^{(\ell,k)} = \frac{\exp(e_{ij}^{(\ell,k)})}{\sum_{t \in \mathcal{N}(i)} \exp(e_{it}^{(\ell,k)})},$$

1086 
$$\mathbf{u}_i^{(\ell,k)} = \sum_{j \in \mathcal{N}(i)} \alpha_{ij}^{(\ell,k)} \mathbf{z}_j^{(\ell,k)}, \quad \mathbf{h}_i^{(\ell+1)} = \phi_\ell(\text{AGG}_k(\mathbf{u}_i^{(\ell,k)})),$$

1087  
1088  
1089  
1090  
1091  
1092 where  $\mathbf{W}$  denote learnable weights,  $\mathbf{a}^{(\ell,k)\top}$  is a single-layer feedforward neural network and  $\text{AGG}_k$  is concatenation in hidden layers and averaging/sum in the final layer. For node  $i$ , the contribution from neighbor  $j$ 's feature  $f$  to output coordinate  $r$  in layer  $\ell$ , head  $k$ , *before* the activation function is  $C_{i \leftarrow j, f \rightarrow r}^{(\ell,k)} = \alpha_{ij}^{(\ell,k)} W_{r,f}^{(\ell,k)} h_{j,f}^{(\ell)}$ . Summing over  $j$  yields per-feature importances  $C_i^{(\ell,k),\text{feat}} \in \mathbb{R}^{F_\ell \times F'_\ell}$ ; summing over  $f$  yields per-neighbor importances  $C_i^{(\ell,k),\text{neigh}} \in \mathbb{R}^{N \times F'_\ell}$ . We pass the pre-activations through a local linear gate  $G_i^{(\ell,k)} = \text{diag}(\phi'_\ell(\mathbf{u}_i^{(\ell,k)}))$  to account for the nonlinearity at the operating point, where  $\phi'_\ell$  is the derivative of the activation function used in layer  $\ell$ .1093  
1094  
1095  
1096  
1097  
1098  
1099  
1100 For example, for two-layer GAT, let layer 1 have  $K_1$  heads of width  $F'_1$  (concatenated width  $K_1 F'_1$ ), and layer 2 have a single head of width  $F'_2$  (no concatenation). Denote  $\mathbf{W}^{(1,k)} \in \mathbb{R}^{F'_1 \times F_0}$ ,  $\mathbf{W}^{(2)} \in \mathbb{R}^{F'_2 \times (K_1 F'_1)}$ , and the layer-1 local gate entries by  $G_{j,q}^{(1,k)} = \phi'_1(u_{j,q}^{(1,k)})$ . Then the contribution from source node  $u$ 's input feature  $f$  to the *layer-2 pre-activation* coordinate  $r$  at target node  $i$  is

1101  
1102  
1103  
1104  
1105  
1106 
$$C_i[u, f \rightarrow r] = \sum_{j \in \mathcal{N}(i)} \alpha_{ij}^{(2)} \sum_{k=1}^{K_1} \sum_{q=1}^{F'_1} W_{r, (k-1)F'_1 + q}^{(2)} G_{j,q}^{(1,k)} \alpha_{ju}^{(1,k)} W_{q,f}^{(1,k)} h_{u,f}^{(0)}.$$

1107  
1108  
1109 If the final embedding is defined *post-activation* for layer 2, multiply the right-hand side by the  
1110 layer-2 gate  $G_{i,r}^{(2)} = \phi'_2(u_{i,r}^{(2)})$ .
