Paper under double-blind review

ABSTRACT

This study aims to analyze the global structure of the functional subgraph of DNNs using tools from topological data analysis (TDA), namely persistent homology (PH) and the Betti curve similarity. Using these methods we present an empirical study on the application of TDA to DNNs in order to gain a better understanding of their architecture and to provide a framework for a similarity measure between DNNs. The study is conducted by training several convolutional neural networks (CNNs) on disjoint subsets of the ImageNet dataset and then by analyzing the structure of their functional graphs across datasets using the Betti curve similarity. Results show that the Betti curve similarity is able to distinguish between different DNN models across datasets and can be a tool for detecting a departure from previous internal representations of those datasets, providing a new method for the analysis of DNNs and a potential path forward for their theoretical development.

1 INTRODUCTION

With the seemingly ubiquitous implementation of deep neural network (DNN) algorithms in modern applications, it has become increasingly important for scientists and practitioners of deep learning, to develop methods for the analysis and scrutability of these algorithms. There have already been various attempts, and small triumphs, with tools such as SHAP values, LIME and XNN (Agarwal and Das, 2020), to name a few, but a complete framework for the scrutability of DNNs has yet to emerge. The sheer size of these DNNs is one of the major reasons why they remain inscrutable, and recent trends seem to indicate that DNNs will only become larger, thus exacerbating this problem.

For these particular reasons we show that a candidate tool for analyzing the global structure of DNNs is persistent homology (PH) and its corresponding summary statistic, the Betti curve. Both of these originate from topological data analysis (TDA), a branch of abstract topology composed of tools for computing the global structure of data. To demonstrate their uses in deep learning, we modify and add upon work by Corneanu et al. (2019) by analyzing the functional graphs of convolutional neural networks (CNNs) and comparing those graphs across time, i.e. epochs, and datasets. This is done by first training several distinct CNNs on disjoint datasets, extracting their activations on the respective testing data, reducing the activation data via a k -means++ algorithm, processing this reduced data using persistent homology, and finally comparing our results using their respective Betti curves, as seen in Figure 1.

2 METHODS

The proposed analysis begins with training a series of CNNs on disjoint subsets of the ILSVRC2017 dataset (Russakovsky et al., 2015), commonly known as ImageNet. The global structure of the CNNs' functional graphs across datasets and epochs are then analyzed using PH and the Betti curve similarity. For reproducibility, the details of the data, the CNN models, and the TDA tools that are used in the study along with the random seed are provided. The code used for the study is largely a modification of the previous work by Corneanu et al. (2019), which provides the scaffolding for the models, data loaders, training, and activation extraction. Our modifications are available here at GitHub and the data is available for download at ImageNet. All of the packages used in the study are listed in the REQUIREMENTS.TXT file in the GitHub repository.

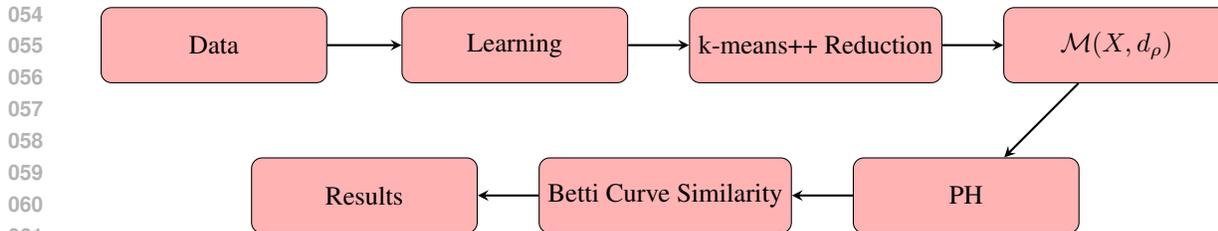

Figure 1: Flowchart of the study where we (1) train several distinct CNNs on disjoint datasets, (2) extract their activations on the respective testing data, (3) reduce the activation data via a k -means++ algorithm, (4) process this reduced data using persistent homology, and (5) comparing our results using their respective Betti curves.

Throughout the study the PyTorch library is used for the implementation of models, datasets, data transformation, and data loaders. The study is conducted on a supercomputing cluster utilizing a single node with two 64-core AMD EPYC 7763 (2.45 GHz) processors with 512 GB of RAM each, and two NVIDIA A100 GPUs with 80 GB of memory each. A full experiment on a given dataset, excluding training, utilizing seven epochs for computation, averages 66 minutes across models.

2.1 DATA

The machine learning task studied here is image classification over ten categories. In order to compare CNN models across subsets of data and epochs, a dataset is required that is large enough to be divided into several subsets (in our case 30 in order to provide a statistically significant sample size without incurring excessive computational overhead) of training and test instances. For its size, availability and ease of use, ImageNet is a natural choice.

The original ImageNet training dataset consists of 1.2 million images, each of which is labeled with one of 1000 categories. The original test dataset consists of 50,000 images, each of which is also labeled with one of its respective categories and where each category contains 50 images. The training dataset is balanced so that each category is represented by the same number of instances, in this case 732 (this being the number of samples in the category with the fewest number of images).

Thirty disjoint subsets of ten categories each are randomly selected using seed 1234; these subsets are then held constant throughout the entire experiment in order to compare the CNN models across the different subsets. Because the data set contains images of varying heights and widths, every image is resized to be 64×64 pixels. All images are then standardized by subtracting the mean and dividing by the standard deviation of the respective training subset. This ensures that the results are consistent with standard practice and that no data leakage occurs between the training and test sets. At training time, the subsets are augmented by randomly flipping the images horizontally and adding random color jitter in order to help prevent overfitting and improve the generalization of the models.

2.2 TRAINING

Four different CNN models are trained across all of the subsets: an extended LeNet model, an AlexNet model, a VGG-16 model, and a ResNet-18 model. This allows us to compare the global structure of the CNNs' functional graphs across the different models, subsets, and epochs. Each of the model's architectures are essentially the same as their original counterparts with the exception of the extended LeNet model, which has an additional two linear layers. This is done to increase the accuracy of the extended LeNet model and enable better comparability between it and the other models. As expected, the extended LeNet model performs the worst out of the four models, with the ResNet-18 model performing the best, in terms of accuracy. Figure 2 shows the average accuracy of each of the models across the different subsets. Note that the models are trained using the same hyperparameters and optimizer settings, which are detailed below.

During training subsets are randomly sampled using a batch size of 100. Each of the models is trained using the Adam optimizer with a learning rate of 0.001 and a weight decay of 0.0005. Cross-entropy

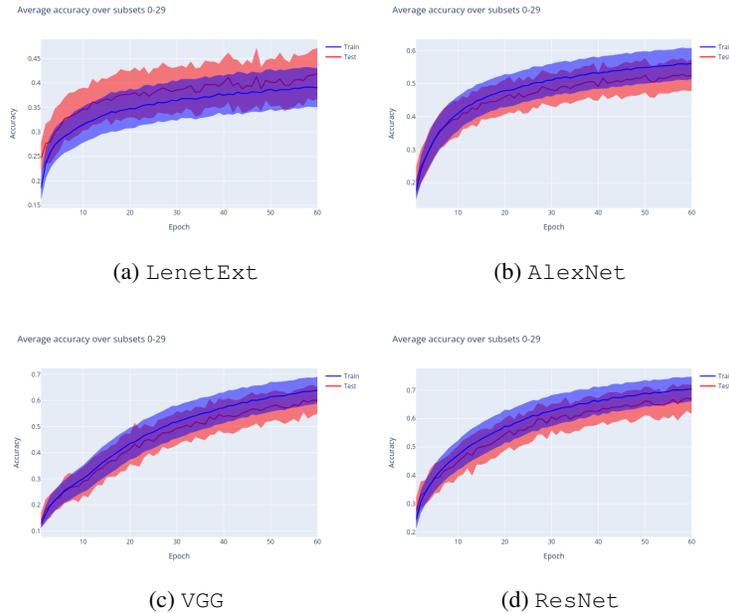

Figure 2: Average accuracies of our models over all subsets.

loss is used to calculate the loss between the predicted and actual labels, and training lasts for 60 epochs, with model weights saved for epochs 0, 10, 20, 30, 40, 50, and 60.

2.3 NON-LINEAR DIMENSIONALITY REDUCTION

In order to make the analysis more computationally feasible, the number of neuron activations from each of the layers of the CNNs is reduced using a PyTorch GPU accelerated k -Means++ algorithm (Omer, 2020). This reduction allows the construction and PH computation of the functional graphs in a reasonable amount of time. k -Means++ was chosen as the reduction technique due to its non-linear nature and its previous success in reducing the dimensionality of point clouds for PH analysis (Malott and Wilsey, 2019).

In order to construct the functional graphs of the CNNs for a given subset, neuron activations are extracted from each of the layers of the network for each of the images in the test set by passing the images (transformed by the corresponding training set transform) through the CNNs and then extracting the neuron activations from each of the layers. The activations are then stored in an array of size $M \times N$, where M is the number of images in the test set and N is the aggregated number of neuron activations from each layer. Any neuron activations whose variance is zero are discarded, since these activations do not contribute to the global structure of the functional graph due to the fact that the correlation between them and other neuron activations is always zero. The neuron activations are then prepared for the k -Means++ algorithm through standardization.

To reduce the number of the neuron activations for each model, the k -Means++ algorithm was used to cluster the neuron activations into 1000 clusters¹. Dimensionality reduction is effected by replacing each neuron activation in a cluster with the neuron activation which is closest to the cluster’s centroid. These neuron activations are then used as the reduced set for the PH analysis, which allows us to construct the functional graphs of the CNNs. Analysis of the silhouette scores for the clusters for each of the models show that the clusters were poorly separated, which in turn shows that the means of the neuron activations are not well-separated.

¹Given the limitations on our computational resources and the complexity of the PH analysis, 1000² activations is the largest number of points that we currently can feasibly analyze using PH.

This reduction in the number of the neuron activations introduces some approximation error into the analysis. However, we argue that the k -Means++ algorithm is able to capture the global structure of the neuron activations in a non-linear way. It has also been argued that the local structure of the neuron activations is not as important as the global structure, since the local structure is more representative of overfit in the model (Corneanu et al., 2019). Therefore, we believe that the k -Means++ reduction is a suitable method for the analysis of the global structure of the functional graphs of the CNNs, which is the main focus of our study.

2.4 FINITE METRIC SPACES AND FUNCTIONAL GRAPHS

A **finite metric space** is a finite set of points X equipped with a function $d_X : X \times X \rightarrow \mathcal{R}^+$ that satisfies the properties of a metric, i.e., non-negativity, symmetry, and the triangle inequality. Since the set of points is finite, we can also completely describe the metric by a distance matrix D_X where $(D_X)_{i,j} = d_X(x_i, x_j)$ for all $x_i, x_j \in X$. In this way, we can represent the finite metric space as a weighted graph, where the vertices are the points of the metric space and the edge weights are the distances between the points.

We formalize the functional graph of a DNN as a finite metric space, where the points are given by the neuron activations of the DNN and the distance between two activations is given by

$$d_\rho(\mathbf{a}_i, \mathbf{a}_j) = \sqrt{1 - |\rho(\mathbf{a}_i, \mathbf{a}_j)|} \quad (1)$$

where $\rho(\mathbf{a}_i, \mathbf{a}_j)$ is the correlation between the neuron activations \mathbf{a}_i and \mathbf{a}_j . We note that the distance function d_ρ satisfies all properties of a metric except for positivity, since d_ρ equaling 0 does not imply that the inputs are the same (López De Prado, 2016). Further, d_ρ is satisfied by several different correlation functions, such as the Pearson and the Spearman correlation. For our study, we use the Spearman correlation as our correlation function ρ , since it is able to capture both linear and non-linear relationships and does not require that the neuron activations be normally distributed (Kutner, 2005).

In order to construct the weighted graph representing the functional graph of a given network `net`, we first took its reduced set of neuron activations from 2.3 and constructed its distance matrix D_{net} using equation 1. With the distance matrix D_{net} we then calculated the persistent homology of the functional graph of `net`.

2.5 TOPOLOGICAL DATA ANALYSIS

Topological data analysis is a framework for analyzing the underlying topological space of a given dataset. It comprises a suite of tools from abstract topology used to construct and count the combinatorial objects which model the structure of topological spaces. In our case, we use the Giotto-tda library (Tauzin et al., 2020) to calculate the PH of the functional graphs of the CNNs and extract the Betti curves from their persistence diagrams. The Betti curves are then used to calculate the Betti curve similarity between the CNN models across the different subsets and epochs. We provide a quick overview of terminology and concepts from TDA from which we derive the necessary tools (Edelsbrunner and Harer, 2010).

Let d be a positive integer and let $\{x_0, x_1, \dots, x_n\} \subset \mathbb{R}^d$ be a finite set of points. An **n -simplex** is the convex hull of $n+1$ affinely independent points, often denoted by $\sigma = [x_0, x_1, \dots, x_n]$ where the dimension of σ is n . A **face** of σ is any of the simplices of equal or lesser dimension that are contained in σ and is often denoted by $\tau \leq \sigma$. The **boundary** of σ is the union of all proper faces of σ where a **proper face** is simply a face of strictly lesser dimension, denoted $\tau < \sigma$. A **simplicial complex** K then, is a finite collection of simplices such that if $\sigma \in K$ and $\tau \leq \sigma$, then $\tau \in K$, and if $\sigma_1, \sigma_2 \in K$, then $\sigma_1 \cap \sigma_2$ is a face of both or is empty.

Let K be a simplicial complex and let $C_n(K)$ be the free abelian group generated by the n -simplices of K . The objects of $C_n(K)$ are called **n -chains** and are formal sums $c = \sum_{i=1}^n a_i \sigma_i$ where $a_i \in \mathbb{Z}_2$ and σ_i is an n -simplex of K . For any two elements $c_1, c_2 \in C_n(K)$, addition is defined similarly to that of polynomials, i.e., $c_1 + c_2 = \sum_{i=1}^n (a_i + b_i) \sigma_i$. Thus, the n -chains of $C_n(K)$ form a vector space over \mathbb{Z}_2 and are known as **chain groups**.

The **boundary operator** $\partial_n : C_n(K) \rightarrow C_{n-1}(K)$ is a linear map between chain groups. It takes as input an n -chain $c = \sum_{i=1}^n a_i \sigma_i$ and maps it to the $(n-1)$ -chain $\partial_n c = \sum_{i=1}^n a_i \partial_n \sigma_i$. The boundary operator operates on the n -simplex $\sigma = [x_0, x_1, \dots, x_n]$ by

$$\partial_n \sigma = \sum_{i=0}^n (-1)^i [x_0, \dots, \hat{x}_i, \dots, x_n] \quad (2)$$

where \hat{x}_i denotes the removal of the i -th vertex of the simplex; essentially taking an n -chain and sending it to its boundary.

Given a simplicial complex K and a dimension p , the p -th boundary operator ∂_p is used to define what are known as **cycles** and **boundaries** of the chain group $C_p(K)$, written $Z_p(K)$ and $B_p(K)$, respectively.

A p -chain $c \in C_p(K)$ is a cycle if $\partial_p c = 0$ and is a boundary if there exists a $(p+1)$ -chain $b \in C_{p+1}(K)$ such that $\partial_{p+1} b = c$. This means then that $Z_p(K) = \ker \partial_p$ and $B_p(K) = \text{im } \partial_{p+1}$, making them both subspaces of $C_p(K)$. Further, due to properties of the boundary operator, it turns out that $B_p(K) \subseteq Z_p(K)$; therefore, the quotient space

$$H_p(K) = Z_p(K)/B_p(K) \quad (3)$$

is defined, and is known as the **p -th homology group** of K . It is essentially the span of the p -cycles which are also not boundaries, and it is used to describe the topological structure of the complex.

In order to construct the PH of a given dataset, we construct its corresponding complex iteratively by adding in simplices a few at a time. This is known as a **filtration** of the complex and must satisfy

$$\emptyset = K_0 \subseteq K_1 \subseteq \dots \subseteq K_n = K, \quad (4)$$

where the indices are dependent on a filtration parameter which is often treated as a time scale.

Given a simplicial complex K and a filtration $\emptyset = K_0 \subseteq K_1 \subseteq \dots \subseteq K_n = K$, the **persistent homology** of K is a measure of the scale of the topological features throughout the filtration, and homology groups of the complex are tracked as the filtration progresses. For a given dimension p and indices $i \leq j$, the p -th persistent homology group of K is defined as

$$H_p^{i,j}(K) = Z_p(K_i)/(B_p(K_j) \cap Z_p(K_i)), \quad (5)$$

with the **p -th persistent Betti number** of a simplicial complex K defined as $\beta_p^{i,j} = \text{rank } H_p^{i,j}(K)$. The Betti numbers of a simplicial complex are used to count the number of p -dimensional generators of space and therefore give a unique summary (up to isomorphism) of its topological structure. It is with these that we construct our Betti curves which allow us to compare networks.

The **Vietoris-Rips complex** V_ϵ , is a simplicial complex that is used to approximate the topology of a finite metric space by constructing simplices from its points. Given a finite metric space (X, d) , the simplices of $V_\epsilon(X)$ are the subsets of X whose diameter is less than or equal to the filtration parameter ϵ , and where the diameter is defined to be the maximum distance between any two points in the subset. The complex is then constructed from these simplices.

This is done by starting with the points of X as our 0-simplices and connecting them with edges if the pairwise distance between them is less than or equal to $\epsilon/2$. We get higher and higher dimensional simplices by continuing to increase ϵ and adding more pairwise intersections between the points. Creating new simplices however comes at a cost, as the youngest simplices are the first to be removed while the eldest live on. This is known as the **Elder Rule** and we say that a simplex is **born** at the filtration parameter ϵ_i and **dies** at ϵ_j if it is added to the complex at ϵ_i and removed at ϵ_j .

For our study we use the multi-threaded Vietoris-Rips complex implementation from Giotto-tda to compute the PH of the finite metric space of each of our functional graphs D_{net} . This particular implementation has been shown to be efficient and scalable for large datasets (Tautzin et al., 2020), even outperforming certain C++ and GPU accelerated implementations.

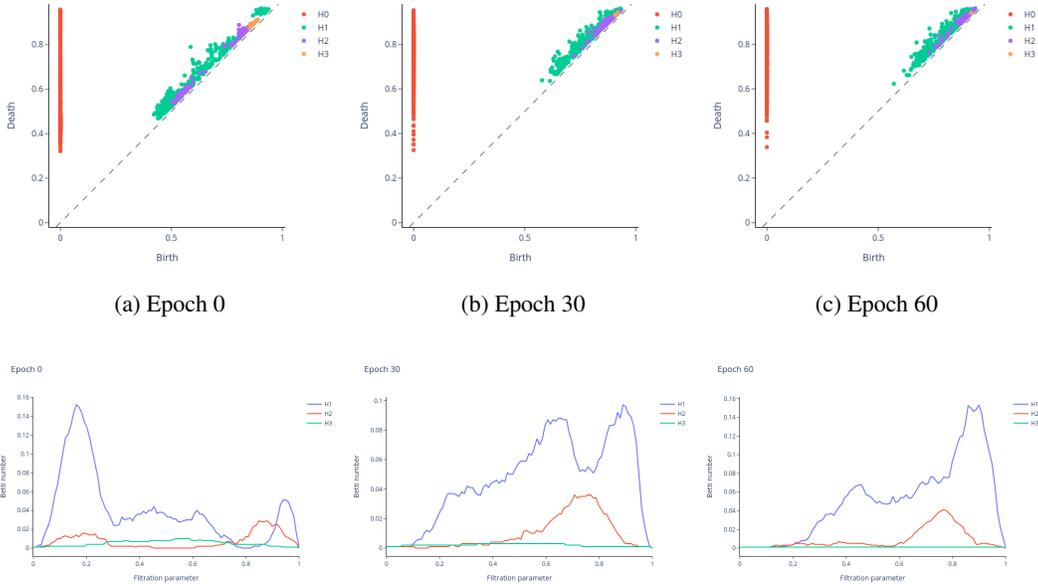

Figure 3: Persistence diagram of the reduced functional graph of ResNet-18 at epochs 0, 30, and 60 for homology dimensions 0–3 and their corresponding Betti curves.

The **persistence diagram** \mathcal{P}_{net} of our Vietoris-Rips complex $V_\epsilon(D_{\text{net}})$ is a visual representation of the Betti numbers of the complex as a function of the filtration parameter, and fully encodes the information from the PH of the complex. As seen in Figure 3, the persistence diagram is a plot of the birth and death times of the topological features of the complex. A feature is considered to be persistent if its death time is reasonably larger than its birth time, and is considered to be noise otherwise, i.e., if it is close to the diagonal. The persistence diagram is then used to calculate the corresponding **Betti curves** according to

$$\beta_{\text{net}}^p(\epsilon) = \left| \{ \mathbf{x} \in \mathcal{P}_{\text{net}}^p \mid x_1 < \epsilon \leq x_2 \} \right| \quad (6)$$

where $\mathcal{P}_{\text{net}}^p$ is the subset of the persistence diagram for the p -th persistent homology group of the complex (Edelsbrunner and Harer, 2010), and where $\epsilon \in [0, 1]$. An example can be seen in Figure 3.

After having calculated the Betti curves β_{net}^p for each of the CNN models across the different subsets and epochs, we calculate the Betti curve similarity between the models. As far as we are aware this is the first time that the Betti curve similarity has been used to compare the global structure of DNNs across datasets and epochs.

The **Betti curve similarity** in dimension p is computed by simply taking the infinity norm of the difference between the Betti curves of two models, i.e.,

$$\text{BCS}_p(\text{net}_1, \text{net}_2) = \left\| \beta_{\text{net}_1}^p - \beta_{\text{net}_2}^p \right\|_\infty \quad (7)$$

3 RESULTS

Here the results of the study are presented for training four different CNN models across 30 disjoint subsets of the ImageNet dataset and analyzing the global structure of their functional graphs using PH and the Betti curve similarity. The Betti curve similarity is able to capture the differences in the global structure of the CNNs’ functional graphs across the different models, subsets, and epochs. The

most interesting results of the study are highlighted here along with a discussion of their implications. Additional results can be found in the supplemental material A.1.

3.1 FUNCTIONAL SIMILARITY ACROSS TIME

Comparing the average unnormalized similarity over time reveals that temporal similarity is quite low at the beginning of training and then typically increases as the models learn the features of the dataset. For example, in Figure 4 the similarity between the ResNet-18 model at epoch 0 and the same model at epoch 60 is quite low, indicating that the global structure of the functional graphs of the network changes over the course of training. A large shift in similarity from epoch 0 to epoch 10 is also evident, where the accuracy of the model is increasing most rapidly. Both of these are to be expected as the network learns the features of the dataset, as seen in Figure 2. Further, in Figure 4, the convergence of the network’s functional graph towards some global structure can be observed, as the similarity between adjacent epochs is increasing. The same phenomenon appears over the other persistent homology dimensions as well (Figure 17). Also of interest is the fact that, on average, the similarity between the models seems to be increasing when compared at the same epoch. This is especially true in the zeroth and first persistent homology dimensions, and can be seen in Figure 5 in which AlexNet and VGG-16 are compared, hinting that the global structures of the functional graphs of the models are becoming more similar as the models are trained and that perhaps on average the models are converging towards the same global structure (Mao et al., 2024).

3.2 FUNCTIONAL SIMILARITY ACROSS DATA

Comparing the average unnormalized similarities across the different subsets of testing data, reveals that the models’ functional graphs are quite dissimilar, i.e., the models’ representation of the subsets are not the same. For certain models and subsets, the similarity was quite low, indicating that the representation for that particular subset was quite different from the others and that the models seem to be representing the features of the dataset in different ways. For example, in Figure 6 it can be seen that the similarity between the ResNet-18 model and the VGG-16 model for subset 11 is very low. Further inspection of the subset itself reveals that the classes in the subset are very distinct (see subsection A.1.5) as compared to others (e.g., subset 25 with three classes of dog), and the accuracy of the models on subset 11 shown in Figure 7 reveals that ResNet-18 outperforms VGG-16 by approximately 5% on the testing set. It can be further observed that for subset 27, a subset with similar classes in terms of morphism, the similarity between the models ResNet-18, VGG-16 and AlexNet was quite high, while they all differ considerably from the extended LeNet model as seen in Figure 8. Looking at the accuracy of the models on this subset however, would not readily reveal this difference, as the models’ performance in terms of accuracy are all distinct, with the extended LeNet model performing most poorly, with AlexNet coming in second worst, as seen in Figure 9. Therefore, it can be concluded that statistically the models are creating distinct internal representations of the testing data across subsets. This is somewhat surprising since the models are not fundamentally different, being simply CNNs of varying sizes, but this also evidences that a simple change to the architecture topology, namely the residual connections in ResNet, can make a large difference for certain datasets.

4 CONCLUSION AND FUTURE WORK

We have introduced some theoretical tools from TDA for analyzing the global functional structure of deep neural networks and have shown that the Betti curve similarity can be a useful tool for the

comparison and analysis of DNNs. As a companion to accuracy and other metrics, the Betti curve similarity can provide a more nuanced understanding of the architecture and training dynamics of DNNs, and could be utilized in ablation studies and hyperparameter tuning. Thus, these tools may allow for more intentional creation of DNNs instead of the current ad hoc approach. We demonstrate some of the potential uses of the Betti curve similarity in our study by analyzing the functional graphs of CNNs. However, it is likely that this approach can be used in the analysis of other machine learning models and other types of data. Further, there are likely many more applications to which it may be applied, including model engineering, model compression, and transfer learning.

1671

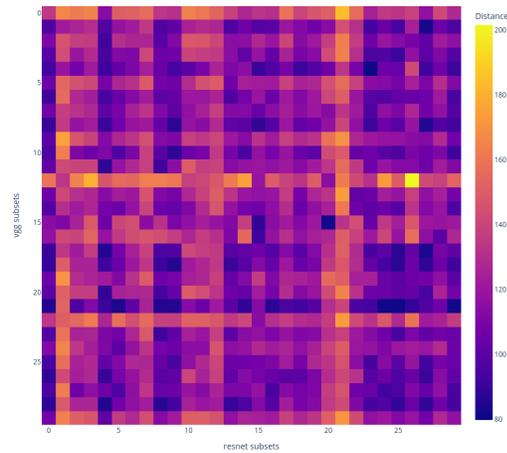

1672

1673

The following is the mapping from the original labels of the ImageNet dataset to the labels used in each of the 30 subsets. The mapping was done in order to ensure that the subsets were disjoint and that the models were trained on different subsets of the dataset. The mapping is as follows:

```
Subset number: 0
Label mapping: n02489166 --> 0 proboscis_monkey
Label mapping: n02097209 --> 1 standard_schnauzer
Label mapping: n09421951 --> 2 sandbar
Label mapping: n02051845 --> 3 pelican
Label mapping: n04004767 --> 4 printer
Label mapping: n02165105 --> 5 tiger_beetle
Label mapping: n04532670 --> 6 viaduct
Label mapping: n02859443 --> 7 boathouse
Label mapping: n03998194 --> 8 prayer_rug
Label mapping: n02815834 --> 9 beaker
```

1674 Original subset labels: [682, 991, 156, 769, 439, 364, 689, 556, 621, 100]
1675
1676 Subset number: 1
1677 Label mapping: n02128925 --> 0 jaguar
1678 Label mapping: n02110341 --> 1 dalmatian
1679 Label mapping: n02100583 --> 2 vizsla
1680 Label mapping: n02099712 --> 3 Labrador_retriever
1681 Label mapping: n02012849 --> 4 crane
1682 Label mapping: n01687978 --> 5 agama
1683 Label mapping: n01631663 --> 6 eft
1684 Label mapping: n03404251 --> 7 fur_coat
1685 Label mapping: n15075141 --> 8 toilet_tissue
1686 Label mapping: n03950228 --> 9 pitcher
1687 Original subset labels: [757, 429, 889, 90, 983, 496, 30, 176, 467, 41]
1688
1688 Subset number: 2
1689 Label mapping: n01843383 --> 0 toucan
1690 Label mapping: n01496331 --> 1 electric_ray
1691 Label mapping: n03467068 --> 2 guillotine
1692 Label mapping: n03425413 --> 3 gas_pump
1693 Label mapping: n02167151 --> 4 ground_beetle
1694 Label mapping: n02939185 --> 5 caldron
1695 Label mapping: n04270147 --> 6 spatula
1696 Label mapping: n06596364 --> 7 comic_book
1697 Label mapping: n03187595 --> 8 dial_telephone
1698 Label mapping: n03729826 --> 9 matchstick
1699 Original subset labels: [567, 517, 930, 984, 959, 445, 673, 676, 623, 417]
1700
1700 Subset number: 3
1701 Label mapping: n02096585 --> 0 Boston_bull
1702 Label mapping: n02097047 --> 1 miniature_schnauzer
1703 Label mapping: n02099429 --> 2 curly-coated_retriever
1704 Label mapping: n04311174 --> 3 steel_drum
1705 Label mapping: n02169497 --> 4 leaf_beetle
1706 Label mapping: n02281787 --> 5 lycaenid
1707 Label mapping: n03920288 --> 6 Petri_dish
1708 Label mapping: n02667093 --> 7 abaya
1709 Label mapping: n06874185 --> 8 traffic_light
1710 Label mapping: n07880968 --> 9 burrito
1711 Original subset labels: [123, 144, 783, 861, 113, 340, 646, 625, 853, 900]
1712
1712 Subset number: 4
1713 Label mapping: n02326432 --> 0 hare
1714 Label mapping: n02091032 --> 1 Italian_greyhound
1715 Label mapping: n03041632 --> 2 cleaver
1716 Label mapping: n01531178 --> 3 goldfinch
1717 Label mapping: n01728920 --> 4 ringneck_snake
