

# A Unified Survey on Anomaly, Novelty, Open-Set, and Out-of-Distribution Detection: Solutions and Future Challenges

Anonymous authors

Paper under double-blind review

## Abstract

Machine learning models often encounter samples that are diverged from the training distribution. Failure to recognize an out-of-distribution (OOD) sample, and consequently assign that sample to an in-class label, significantly compromises the reliability of a model. The problem has gained significant attention due to its importance for safety deploying models in open-world settings. Detecting OOD samples is challenging due to the intractability of modeling all possible unknown distributions. To date, several research domains tackle the problem of detecting unfamiliar samples, including anomaly detection, novelty detection, one-class learning, open set recognition, and out-of-distribution detection. Despite having similar and shared concepts, out-of-distribution, open-set, and anomaly detection have been investigated independently. Accordingly, these research avenues have not cross-pollinated, creating research barriers. While some surveys intend to provide an overview of these approaches, they seem to only focus on a specific domain without examining the relationship between different domains. This survey aims to provide a cross-domain and comprehensive review of numerous eminent works in respective areas while identifying their commonalities. Researchers can benefit from the overview of research advances in different fields and develop future methodology synergistically. Furthermore, to the best of our knowledge, while there are surveys in anomaly detection or one-class learning, there is no comprehensive or up-to-date survey on out-of-distribution detection, which our survey covers extensively. Finally, having a unified cross-domain perspective, we discuss and shed light on future lines of research, intending to bring these fields closer together. All the implementations and benchmarks reported in the paper can be found here : <https://anonymous.4open.science/r/osr-ood-ad-methods-DBFC/README.md> (R2)

## 1 Introduction

Machine learning models commonly make the closed-set assumption, where the test data is drawn *i.i.d* from the same distribution as the training data. Yet in practice, all types of test input data—even those on which we have not trained the classifier—can be encountered. Unfortunately, models can assign misleading confidence values for unseen test samples Sun et al. (2020); Miller et al. (2021); Oza & Patel (2019); Yoshihashi et al. (2019); Yu & Aizawa (2019). This leads to concerns about the reliability of classifiers, particularly for safety-critical applications Hendrycks et al. (2021a). In the literature, several fields attempt to address the issue of identifying the unknowns/anomalies/out-of-distribution data in the open-world setting. In particular, the problems of anomaly detection (AD), Novelty Detection (ND), One-Class Classification (OCC), Out-of-Distribution (OOD) detection, and Open-Set Recognition (OSR) have gained significant attention owing to their fundamental importance and practical relevance. They have been used for similar tasks, although the differences and connections are often overlooked.

Specifically, OSR trains a model on  $K$  classes of a  $N$  class training dataset; then, at the test time, the model is faced with  $N$  different classes of which  $N - K$  are not seen during training. OSR aims to assign correct labels to seen test-time samples while detecting the unseen samples. Novelty detection or one-class classification is an extreme case of open-set recognition, in which  $K$  is 1. In the multi-class classification setting, the problem of OOD detection is canonical to OSR: accurately classify in-distribution (ID) samples

into the known categories and detect OOD data that is semantically different and therefore should not be predicted by the model. However, OOD detection encompasses a broader spectrum of learning tasks (e.g., multi-label classification, reinforcement learning) and solution space (e.g., density estimation), which we comprehensively review in this paper.

While all the aforementioned domains hold the assumption of accessing an entirely normal training dataset, anomaly detection assumes the training dataset is captured in a fully unsupervised manner without applying any filtration; therefore, it might contain some abnormal samples too. However, as abnormal events barely occur, AD methods have used this fact and proposed filtering them during the training process to reach a final semantic space that fully grasps normal features. Despite previous approaches that are mostly used in object detection and image classification domains, this setting is more common in the industrial defect detection tasks, in which abnormal events are rare and normal samples have a shared concept of normality. Fig. 1 depicts an overview of the mentioned domains, in which the differences are shown visually. Note that even if there are differences in the formulation of these domains, they have so much in common, making them used interchangeably.

As an important research area, there have been several surveys in the literature Bulusu et al. (2020); Perera et al. (2021); Ruff et al. (2021); Pang et al. (2020); Chalapathy & Chawla (2019), focusing on each domain independently or providing a very general notion of anomaly detection to cover all different types of datasets. Instead, we offer in-depth explanations for methodologies in respective areas. We make cross-domain bridges by which ideas can be easily propagated and inspire future research. For instance, the idea of using some outlier samples from different datasets to improve task-specific features is called Outlier Exposure in Hendrycks et al. (2019a) or background modeling in Dhamija et al. (2018), and is very similar to semi-supervised anomaly detection in Ruff et al. (2019). Despite the shared idea, all are considered to be novel ideas in their respective domains.

In this survey, we identify the commonalities that address different but related fields. Furthermore, we try to categorize different methods based on general justifications. For instance, some surveys Ruff et al. (2021) categorize methods into different classes, such as distance-based methods and density-based methods. As distance-based methods can be simply converted to density-based ones, one can find this classification ambiguous. **Although some of the mentioned tasks have very close methodological setups, they differ in their testing protocols. Therefore, a comprehensive review of all the methods can better reveal their limitations in practical applications. (R1)** Key to our survey, we describe methods both mathematically and visually to give better insights to both newcomers and experienced researchers. Finally, comprehensive future lines of research are provided both practically and fundamentally to not only address the issues of current methods but also shed light on critical applications of these methods in different fields.

In summary, our main contributions are as follows :

1. Identify the relationship between different research areas that, despite being highly correlated with each other, have been examined separately.
2. Comprehensive methodological analysis of recent eminent research, and providing a clear theoretical and visual explanation for methods reviewed.
3. Performing comprehensive tests on existing baselines in order to provide a solid ground for current and future lines of research.
4. Providing plausible future lines of research and specifying some fundamental necessities of the methods that will be presented in the future such as fairness, adversarial robustness, privacy, data-efficiency, and explainability.

## 2 General Perspectives of Method Categorizations

We consider a dataset with training samples  $(x_1, y_1), (x_2, y_2), \dots$  from the joint distribution  $P_{X,Y}$ , where  $X$  and  $Y$  are random variables on an input space  $\mathcal{X} = \mathbb{R}^d$  and a label (output) space  $\mathcal{Y}$  respectively. In-class

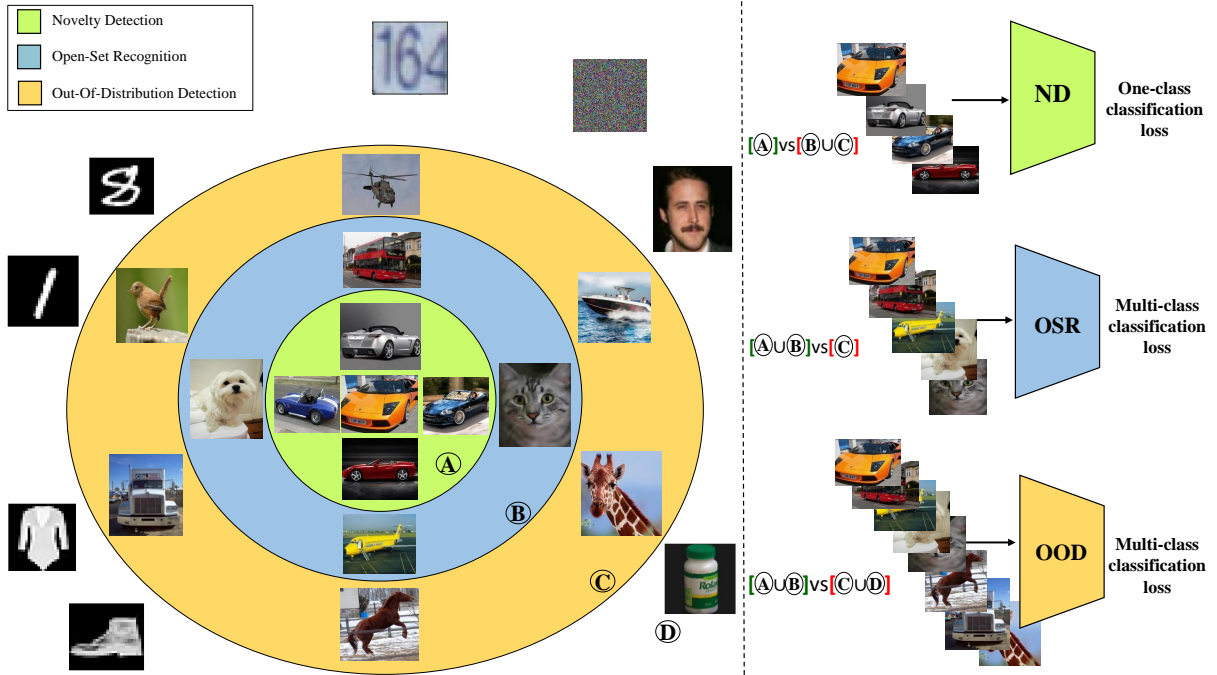

Figure 1: Problem setup for ND, OSR, and OOD from a unified perspective based on the common routine followed in the respective fields. (A), (B) and (C) are sampled from the same training dataset, while (D) is sampled from different datasets. Typically, in ND, all training samples are deemed normal, and share a common semantic (green region), while samples diverged from such distribution are considered as anomalous. Although samples in area (D) can be regarded as potential outliers, only areas (B) and (C) are used as anomalies for the evaluation phase. In OSR, more supervision is available by accessing the label of normal samples. For example "car", "dog", "cat", and "airplane" classes i.e, the union of (A) and (B), are considered as normal while (C) is open-set distribution(see right Figure). Same as ND, (D) is not usually considered an open-set distribution in the field, while there is no specific constraint on the type of open-set distribution in the definition of OSR domain. In the OOD detection, multiple classes are considered as normal, which is quite similar to the OSR. For example, (A), (B), and (C) comprise the normal training distributions, and another distribution that shows a change to some extent with respect to the training distribution is said to be out-of-distribution, which can be (D) in this case. (R1, R2, R3)

(also called "seen" or "normal") domain refers to the training data. In AD or ND, the label space  $\mathcal{Y}$  is a binary set, indicating normal vs. abnormal. During testing, provided with an input sample  $x$ , the model needs to estimate  $P(Y = \text{normal/seen/in-class} \mid X = x)$  in the cases of one-class setting. In OOD detection and OSR for multi-class classification, the label space can contain multiple semantic categories, the model needs to additionally perform classification on normal samples based on the posterior probability  $p(Y = y \mid x)$ . It is worth mentioning that in AD, input samples could contain some noises (anomalies) combined with normals; thus, the problem is converted into a noisy-label one-class classification problem; however, the overall formulation of the detection task still remains the same.

To model the conditional probabilities, the two most common and known perspectives are called **generative modeling** and **discriminative modeling**. While discriminative modeling might be easy for OOD detection or OSR settings since there is access to the labels of training samples; nevertheless, the lack of labels makes AD, ND (OCC) challenging. This is because one-class classification problems have a trivial solution to map each of their inputs regardless of being normal or anomaly to the given label  $Y$  and, consequently, minimize their objective function as much as possible. This issue can be seen in some of the recent approaches such as DSVDDRuff et al. (2018), which maps every input to a single point regardless of being normal or abnormal when it is trained for a large number of training epochs.

**Table 1:** The table summarizes the most notable recent deep learning-based works in different fields, specified by the informative methodological keywords and decision score used in each work. For the methods that have common parts, a shared set of keywords are used to place them on a unitary ground as much as possible. The pros and cons of each methodology are described in detail in the method explanation. (R2, R3)

Taxonomy	Methods	Refrence	Decision Score	Keywords
ND	ALOCC	Sabokroun et al. (2018a)	reconstruction error for input	discriminative-generative, reconstruction-based, adversarial learning, denoising AutoEncoder, Refinement and Detection
	Mem-AE	Gong et al. (2019)	reconstruction error for input	generative, reconstruction-based, Memory-based Representation, sparse addressing technique, hard shrinkage operator
	DeepSvdd	Ruff et al. (2018)	distance of the input to the center of the hypersphere	discriminative, extension of SVDD, compressed features, minimum volume hyper-sphere, Autoencoder
	GT	Golan & El-Yaniv (2018)	sum of Dirichlet probabilities for different transformations of input	self-supervised learning, auxiliary task, self-labeled dataset, geometric transformations, softmax response vector
	CSI	Tack et al. (2020)	cosine similarity to the nearest training sample multiplied by the norm of representation	self-supervised learning, contrastive learning, negative samples, shifted distribution, hard augmentations
	Uninformed Students	Bergmann et al. (2020)	an ensemble of student networks' variance and regression error	knowledge distillation, teacher-student based, transfer learning, self supervised learning, Descriptor Compactness
	CutPaste	Li et al. (2021)	log-density of trained Gaussian density estimator	self-supervised Learning, generative classifiers, auxiliary task, extracting patch-level representations, cutout and scar
	Multi-KD	Salehi et al. (2021b)	discrepancy between the intermediate teacher and student networks' activation values	knowledge distillation, teacher-student, transfer the intermediate knowledge, pretrained network, mimicking different layers
OSR	OpenMax	Bendale & Boulk (2016)	after computing OpenMax probability per channel maximum probability is then selected	Extreme Value Theorem, activation vector, overconfident scores, weibull distribution, Meta-Recognition
	OSRCI	Neal et al. (2018)	probability assigned to class with label $k + 1$ , minus maximum probability assigned to first $k$ class	generative, unknown class generation, classification based, Counterfactual Images, learning decision boundary
	C2AE	Oza & Patel (2019)	minimum reconstruction error under different match vectors, compared with the predetermined threshold	generative, Reconstruction based, class conditional Autoencoder, Extreme Value Theory, feature-wise linear modulations
	CROSR	Yoshihashi et al. (2019)	after computing OpenMax probability per channel maximum probability is then selected	discriminative-generative, classification-reconstruction based , Extreme Value Theorem, hierarchical reconstruction nets
	GDFR	Perera et al. (2020)	by passing the augmented input to the classifier network, and finding maximum activation	discriminative-generative, self-supervised learning, reconstruction based, auxiliary task, geometric transformation
	OpenGan	Kong & Ramanan (2021)	the trained discriminator utilized as an open-set likelihood function	discriminative-generative, unknown class generation, adversarially synthesized fake data, crucial to use a validation set, model selection
	MLS	Vaze et al. (2021)	negation of maximum logit score	discriminative, classification based, between the closed-set and open-set, Fine-grained datasets, Semantic Shift Benchmark(SSB)
OOD	MSP	Hendrycks & Gimpel (2016)	Negation of maximum softmax probability	outlier detection metric, softmax distribution, maximum class probability, classification based, various data domains
	ODIN	Liang et al. (2017)	Negation of maximum softmax probability with temperature scaling	outlier detection metric, softmax distribution, temperature scaling, adding small perturbations, enhancing separability
	A Simple Unified etc.	Lee et al. (2018)	Mahalanobis distance to the closest class-conditional Gaussian	distance based, simple outlier detection metric, small controlled noise, class-incremental learning, Feature ensemble
	OE	Hendrycks et al. (2018)	negation of maximum softmax probability	outlier exposure , auxiliary dataset, classification based, uniform distribution over $k$ classes, various data domains
	Using SSL etc.	Hendrycks et al. (2019a)	negation of maximum softmax probability	self-supervised learning, auxiliary task, robustness to adversarial perturbations, MSP, geometric transformation
	G-ODIN	Hsu et al. (2020)	softmax output's categorical distribution	outlier detection metric, softmax distribution, learning temperature scaling, Decomposed Confidence
	Energy-based OOD	Liu et al. (2020b)	the energy function (a scalar is derived from the logit outputs)	outlier detection metric, hyperparameter-free, The <i>Helmholtz free energy</i> , energy-bounded learning, the Gibbs distribution
	MOS	Wang et al. (2021)	lowest <i>others</i> score among all groups	softmax distribution, group-based Learning, large-scale images, category <i>others</i> , pre-trained backbone
	ReAct	Sun et al. (2021)	after applying ReAct different OOD detection methods could be used, they default to using the energy score.	activation truncation, reducing model overconfidence, compatible with different OOD scoring functions

Some approaches Golan & El-Yaniv (2018); Bergman & Hoshen (2020), however, have made some changes in the formulation of  $P(Y | X)$  to solve this problem. They apply a set of affine transformations on the distribution of  $X$  such that the normalized distribution does not change. Then the summation  $\sum_{i=1}^{|T|} P(T_i | T_i(X))$  is estimated, calculating the aggregated probability of each transformation  $T_i$  being applied on the input  $X$  given the transformed input  $T_i(X)$ , which is equal to  $|T|P(Y | X)$ . This is similar to estimating  $P(Y | X)$  directly; however, it would not collapse and can be used instead of estimating one-class conditional probability. This simple approach circumvents the problem of collapsing; however, it makes the problem depend on the transformations since transformed inputs must not have an intersection with each other as much as possible to satisfy the constraint of normalized distribution consistency. Therefore, as we will show later, OSR methods can employ AD approaches with classification models to overcome their issues. A similar situation holds for the OOD domain.

In generative modeling, AE (Autoencoder)-based, GAN (Generative Adversarial Network)-based, and explicit density estimation-based methods such as auto-regressive and flow-based models are used to model the data distribution. For AEs, there are two important assumptions.

If the auto-encoder is trained solely normal training samples:

- They **would** be able to reconstruct unseen normal test-time samples as precisely as training time ones.
- They **would not** be able to reconstruct unseen abnormal test-time samples as precisely as normal inputs.

Nevertheless, recently proposed AE-based methods show that the above-mentioned assumptions are not always true Salehi et al. (2021a); Gong et al. (2019); Zaheer et al. (2020). For instance, even if AE can reconstruct normal samples perfectly, nonetheless with only a one-pixel shift, reconstruction loss will be high.

Likewise, GANs as another famous model family, are widely used for AD, ND, OCC, OSR, and OOD detection. If a GAN is trained on fully normal training samples, it operates on the following assumptions:

- If the input is **normal** then there **is** a latent vector that, if it is generated, has a low discrepancy with the input.
- If the input is **abnormal** then there **is not** a latent vector that, if it is generated, has a low discrepancy with the input.

Here, the discrepancy can be defined based on the pixel-level MSE loss of the generated image and test time input or more complex functions such as layer-wise distance between the discriminator’s features when it is fed generated image and test-time input. Although GANs have proved their ability to capture semantic abstractions of a given training dataset, they suffer from mode-collapse, unstable training process, and irreproducible result problems Arjovsky & Bottou (2017).

Finally, auto-regressive and flow-based models can be used to explicitly approximate the data density and detect abnormal samples based on their assigned likelihood. Intuitively, normal samples must have higher likelihoods compared to abnormal ones; however, as will be discussed later, auto-regressive models even assign a higher amount of likelihoods to abnormal samples while they have not seen any of them at their training process, which results in a weak performance in AD, ND, OSR, and OOD detection. We will be reviewing solutions to this problem in subsequent sections. To address this issue, several remedies have been proposed in the OOD domain, which can be used in OSR, AD, and ND; however, considering the fact that OOD detection’s prevalent testing protocols might be pretty different from other domains such as AD or ND, more evaluations on their reliability are needed. [In Table 1, a summary of the most notable papers reviewed in this work is presented, and their contributions with respect to the methodological categorization provided in the paper are specified.](#) (R2, R3)

### 3 Non Deep Learning-Based Approaches (R3)

In this section, some of the most notable traditional methods used to tackle the problem of anomaly detection are explained. All other sections are based on the new architectures that are mainly based on deep learning.

#### 3.1 Isolation Forests Liu et al. (2008):

Like Random Forests, Isolation Forests (IF) are constructed using decision trees. It is also an unsupervised model because there are no labels that have been predefined. Isolation Forests were created with the notion that anomalies are "few and distinct" data points. An Isolation Forest analyzes randomly sub-sampled data in a tree structure using attributes chosen at random. Because further-reaching samples required more cuttings to separate, they are less likely to be outliers. Similarly, samples that end up in shorter branches exhibit anomalies because the tree could distinguish them from other data more easily. Fig. 2 depicts the overall procedure of this work.

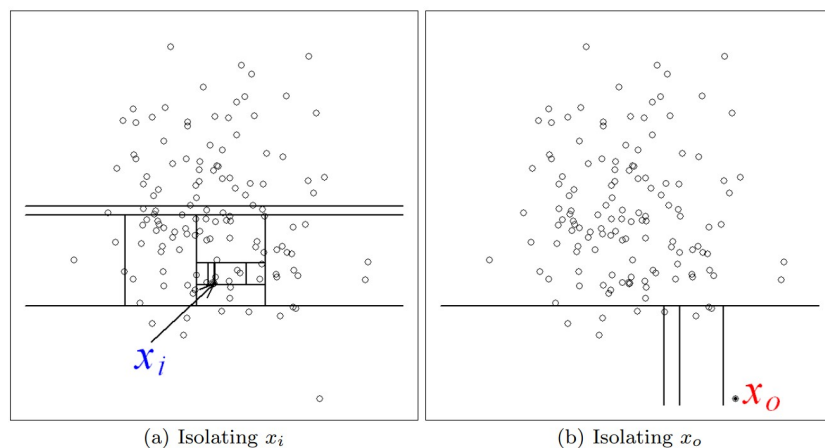

Figure 2: An overview of the isolation forest method is shown. Anomalies are more susceptible to isolation and hence have short path lengths. A normal point  $x_i$  requires twelve random partitions to be isolated compared to an anomaly  $x_o$  that requires only four partitions to be isolated.

### 3.2 DBSCAN Ester et al. (1996):

Given a set of points in a space, it combines together points that are densely packed together (points with numerous nearby neighbors), identifying as outliers those that are isolated in low-density regions. The steps of the DBSCAN algorithm are as follows: (1) Identify the core points with more than the minimum number of neighbors required to produce a dense zone. (2) On the neighbor graph, find the related components of core points, ignoring all non-core points. (3) If the cluster is a neighbor, assign each non-core point to it, otherwise assign it to noise. Fig. 3 depicts the overall procedure of this work.

Figure 3: The minimal number of points required to generate a dense zone in this figure is four. Because the area surrounding these points in a radius contains at least four points, Point A and the other red points are core points (including the point itself). They constitute a single cluster because they are all reachable from one another. B and C are not core points, but they may be reached from A (through other core points) and hence are included in the cluster. Point N is a noise point that is neither a core nor reachable directly.

### 3.3 LOF: Identifying Density-Based Local Outliers Breunig et al. (2000):

The local outlier factor is based on the concept of a local density, in which locality is determined by the distance between  $K$  nearest neighbors. One can detect regions of similar density and points that have a significantly lower density than their neighbors by comparing the local density of an object to the local densities of its neighbors. These are classified as outliers. The typical distance at which a point can be "reached" from its neighbors is used to estimate the local density. The LOF notion of "reachability distance" is an extra criterion for producing more stable cluster outcomes. The notions of "core distance" and "reachability distance", which are utilized for local density estimation, are shared by LOF and DBSCAN.

### 3.4 OC-SVM Schölkopf et al. (1999):

Primary AD methods would use statistical approaches such as comparing each sample with the mean of the training dataset to detect abnormal inputs, which imposes an ungeneralizable and implicit Gaussian distribution assumption on the training dataset. In order to reduce the number of presumptions or relieve the mentioned deficiencies of traditional statistical methods, OC-SVM Schölkopf et al. (1999) was proposed. As the name implies, OC-SVM is a one-class SVM maximizing the distance of training samples from the origin using a hyper-plane, including samples on one side and the origin on its other side. Eq. 1 shows the primal form of OC-SVM that attempts to find a space in which training samples lie on just one side, and the more distance of origin to the line, the better solution is found for the optimization problem.

$$\begin{aligned} \min_{w, \rho, \xi_i} \quad & \frac{1}{2} \|w\|^2 + \frac{1}{vn} \sum_1^n \xi_i - \rho \\ \text{subject to} \quad & (w \cdot \Phi(x_i)) \geq \rho - \xi_i, i \in 1, \dots, n \\ & \xi_i \geq 0, i \in 1, \dots, n \end{aligned} \tag{1}$$

Finding a hyper-plane appears to be a brilliant approach for imposing a shared normal restriction on the training samples. But unfortunately, because half-space is not compact enough to grasp unique shared normal features, it generates a large number of false negatives. (R3) Therefore, similarly, Support Vector Data Description (SVDD) tries to find the most compact hyper-sphere that includes normal training samples. This is much tighter than hyper-plan, thus finds richer normal features, and is more robust against unwanted noises as Eq. 2 shows. Both of the mentioned methods offer soft and hard margin settings, and in the former, despite the latter, some samples can cross the border and remain outside of it even if they are normal. (R3) OC-SVM has some implicit assumptions too; for example, it assumes training samples obey a shared concept, which is conceivable due to the one-class setting. Also, it works pretty well on the AD setting in which the number of outliers is significantly lower than normal ones however fails on high dimensional datasets.

$$\begin{aligned} \min_{R, a} \quad & C \sum_{i=1}^n \xi_i + R^2 \\ \text{subject to} \quad & \|\phi(x_i) - a\|^2 \leq R^2 + \xi_i, i \in 1, \dots, n \\ & \xi_i \geq 0, i \in 1, \dots, n \end{aligned} \tag{2}$$

## 4 Anomaly and Novelty Detection

Anomaly Detection (AD) and Novelty Detection (ND) have been used interchangeably in the literature, with few works addressing the differences Perera et al. (2019); Xia et al. (2015); Wang et al. (2019). There are specific inherent challenges with anomaly detection that contradict the premise that the training data includes entirely normal samples. In physical investigations, for example, measurement noise is unavoidable; as a result, algorithms in an unsupervised training process must automatically detect and focus on the normal samples. (R3) However, this is not the case for novelty detection problems. There are many applications in

which providing a clean dataset with minimum supervision is an easy task. While these domains have been separated over time, their names are still not appropriately used in literature. We review them here in a shared section.

Interests in anomaly detection go back to 1969 Grubbs (1969), which defines anomaly/outlier as “**samples that appear to deviate markedly from other members of the sample in which it occurs**”, explicitly assuming the existence of an underlying shared pattern that a large fraction of training samples follow. This definition has some ambiguity. For example, one should define a criterion for the concept of deviation or make the term “markedly” more quantitative.

To this end, there has been a great effort both before and after the advent of deep learning methods to make the mentioned concepts more clear. To find a sample that deviates from the trend, adopting an appropriate distance metric is necessary. For instance, deviation could be computed in a raw pixel-level input or in a semantic space that is learned through a deep neural network. Some samples might have a low deviation from others in the raw pixel space but exhibit large deviations in representation space. Therefore, choosing the right distance measure for a hypothetical space is another challenge. Finally, the last challenge is choosing the threshold to determine whether the deviation from normal samples is significant.

#### 4.1 Anomaly Detection With Robust Deep Auto-encoders Zhou & Paffenroth (2017):

This work trains an AutoEncoder (AE) on a dataset containing both inliers and outliers. The outliers are detected and filtered during training, under the assumption that inliers are significantly more frequent and have a shared normal concept. This way, the AE is trained only on normal training samples and consequently poorly reconstructs abnormal test time inputs. The following objective function is used:

$$\begin{aligned} \min_{\theta} & \|L_D - D_{\theta}(E_{\theta}(L_D))\|_2 + \lambda \|S\|_1 \\ \text{s.t.} & X - L_D - S = 0, \end{aligned} \quad (3)$$

where E and D are encoder and decoder networks, respectively.  $L_D$  is supposed to be the inlier part and  $S$  the outlier part of the training data  $X$ . However, the above optimization is not easily solvable since  $S$  and  $\theta$  need to be optimized jointly. To address this issue, the Alternating Direction Method of Multipliers (ADMM) is used, which divides the objective into two (or more) pieces. At the first step, by fixing  $S$ , an optimization problem on the parameters  $\theta$  is solved such that  $L_D = X - S$ , and the objective is  $\|L_D - D_{\theta}(E_{\theta}(L_D))\|_2$ . Then by setting  $L_D$  to be the reconstruction of the trained AE, the optimization problem on its norm is solved when  $S$  is set to be  $X - L_D$ . Since the  $L_1$  norm is not differentiable, a proximal operator is employed as an approximation of each of the optimization steps as follows:

$$\text{prox}_{\lambda, L_1}(x_i) = \begin{cases} x_i - \lambda & x_i > \lambda \\ x_i + \lambda & x_i < -\lambda \\ 0 & -\lambda \leq x_i \leq \lambda \end{cases} \quad (4)$$

Such a function is known as a *shrinkage operator* and is quite common in  $L_1$  optimization problems. The mentioned objective function with  $\|S\|_1$  separates only unstructured noises, for instance, Gaussian noise on training samples, from the normal content in the training dataset. To separate structured noises such as samples that convey completely different meaning compared to the majority of training samples,  $L_{2,1}$  optimization norm can be applied as:

$$\sum_{j=1}^n \|x_j\|_2 = \sum_{j=1}^n \left( \sum_{i=1}^m |x_{ij}|^2 \right)^{1/2}, \quad (5)$$

with a proximal operator that is called block-wise soft-thresholding function Mosci et al. (2010). At the test time, the reconstruction error is employed to reject abnormal inputs.

## 4.2 Adversarially Learned One-Class Classifier for Novelty Detection (ALOCC) Sabokrou et al. (2018a):

In this work, it is assumed that a fully normal training sample is given, and the goal is to train a novelty detection model using them. At first,  $(\mathcal{R})$  as a Denoising Auto Encoder (DAE) is trained to (1) decrease the reconstruction loss and (2) fool a discriminator in a GAN-based setting. This helps the DAE to produce high-quality images instead of blurred outputs Larsen et al. (2016). This happens because, on the one hand, the AE model loss explicitly assumes independent Gaussian distributions for each of the pixels. And on the other hand, true distributions of pixels are usually multi-modal, which forces the means of Gaussians to settle in between different modes. Therefore, they produce blurry images for complex datasets. To address this issue, AEs can be trained in a GAN-based framework to force the mean of each of Gaussians to capture just one mode of its corresponding true distribution. Moreover, by using the discriminator’s output ( $\mathcal{D}$ ) instead of the pixel-level loss, normal samples that are not properly reconstructed can be detected as normal. This loss reduces the False Positive Rate (FPR) of the vanilla DAE significantly. The objective function is as follows:

$$\begin{aligned} \mathcal{L}_{\mathcal{R}+\mathcal{D}} &= \min_{\mathcal{R}} \max_{\mathcal{D}} \left( \mathbb{E}_{X \sim p_t} [\log(\mathcal{D}(X))] + \right. \\ &\quad \left. \mathbb{E}_{\tilde{X} \sim p_t + \mathcal{N}_\sigma} (\log(1 - \mathcal{D}(\mathcal{R}(\tilde{X}))) \right) \\ \mathcal{L}_{\mathcal{R}} &= \|X - X'\|^2 \\ \mathcal{L} &= \mathcal{L}_{\mathcal{R}+\mathcal{D}} + \mathcal{L}_{\mathcal{R}}, \end{aligned} \quad (6)$$

where  $X'$  is the reconstructed output of the decoder, and  $p_t$  is the distribution of the target class (i.e., normal class). This helps the model to not only have the functionality of AEs for anomaly detection but also produces higher quality outputs. Furthermore, detection can be done based on  $\mathcal{D}(\mathcal{R}(X))$  as mentioned above. Fig. 4 depicts the overall architecture of this work.

An extended version of ALOCC, where the  $\mathcal{R}(X)$  network has been formed as a Variational AE is presented in Sabokrou et al. (2020). Besides, the ALOCC can not process the whole of its input data (images or video frames) at one step and needs the test samples to divide into several patches. Processing the patches makes the method computationally expensive. To address this problem, AVID Sabokrou et al. (2018b) was proposed to exploit a fully convolutional network as a discriminator (i.e.,  $\mathcal{D}$ ) to score (and hence detect) all abnormal regions in the input frame/image all at once.

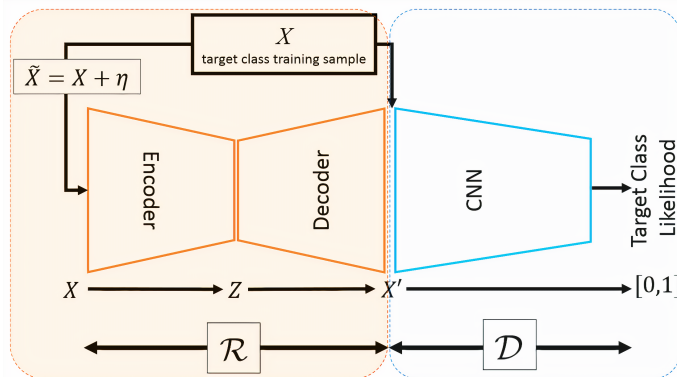

Figure 4: An overview of the ALOCC method is shown. This work trains an autoencoder that fools a discriminator in a GAN-based setting. This helps the AE to make high-quality images instead of blurred outputs. Besides, by using the discriminator’s output, a more semantic similarity loss is employed instead of the pixel-level  $L_2$  reconstruction loss.

### 4.3 One-Class Novelty Detection Using GANs With Constrained Latent Representations (OC-GAN) Perera et al. (2019):

As one of the challenges, AE trained on entirely normal training samples could reconstruct unseen abnormal inputs with even lower errors. To solve this issue, this work attempts to make the latent distribution of the encoder ( $\text{EN}(\cdot)$ ) similar to the uniform distribution in an adversarial manner:

$$l_{\text{latent}} = -(\mathbb{E}_{s \sim \mathcal{U}(-1,1)}[\log(D_l(s))] + \mathbb{E}_{x \sim p_x}[\log(1 - D_l(\text{EN}(x+n)))]), \quad (7)$$

where  $n \sim N(0, 0.2)$ , and  $D_l$  is the latent discriminator. The discriminator forces the encoder to produce uniform distribution on the latent space. Similarly, the decoder ( $\text{De}(\cdot)$ ) is forced to reconstruct in-class outputs for any latent value sampled from the uniform distribution as follows :

$$l_{\text{visual}} = -(\mathbb{E}_{s \sim \mathcal{U}(-1,1)}[\log(D_v(\text{De}(s)))] + \mathbb{E}_{x \sim p_l}[\log(1 - D_v(x))]), \quad (8)$$

where  $D_v$  is called visual discriminator.

Intuitively, the learning objective distributes normal features in the latent space such that the reconstructed outputs entirely or at least roughly resemble the normal class for both normal and abnormal inputs. Also, another technique called *informative negative sample mining* is employed on the latent space to actively seek regions that produce images of poor quality. To do so, a classifier is trained to discriminate between the reconstructed outputs of the decoder and fake images, which are generated from randomly sampled latent vectors. To find informative negative samples, the algorithm (see Fig. 5) starts with a random latent-space sample and uses the classifier to assess the quality of the generated image. After that, the algorithm solves an optimization in the latent space to make the generated image such that the discriminator detects it as fake. Finally, the negative sample is used to boost the training process.

As in previous AE-based methods, reconstruction loss is employed in combination with the objective above. Reconstruction error is used as the test time anomaly score.

### 4.4 Latent Space Autoregression for Novelty Detection (LSA) Abati et al. (2019):

This work proposes a concept called "surprise" for novelty detection, which specifies the uniqueness of input samples in the latent space. The more unique a sample is, the less likelihood it has in the latent space, and subsequently, the more likely it is to be an abnormal sample. This is beneficial, especially when there are many similar normal training samples in the training dataset. [To minimize the MSE error for visually identical training samples, AEs often learn to reconstruct their average as the outputs. This can result in fuzzy results and large reconstruction errors for such inputs. \(R3\)](#) Instead, by using the surprise loss in combination with the reconstruction error, the issue is alleviated. Besides, abnormal samples are usually more surprising, and this increases their novelty score. Surprise score is learned using an auto-regressive model on the latent space, as Fig. 6 shows. The auto-regressive model ( $h$ ) can be instantiated from different architectures, such as LSTM and RNN networks, to more complex ones. Also, similar to other AE-based methods, the reconstruction error is optimized. The overall objective function is as follows:

$$\begin{aligned} \mathcal{L} &= \mathcal{L}_{\text{Rec}}(\theta_E, \theta_D) + \lambda \cdot \mathcal{L}_{\text{LLK}}(\theta_E, \theta_h) \\ &= \mathbb{E}_X [||x - \hat{x}||^2 - \lambda \cdot \log(h(z; \theta_h))] \end{aligned} \quad (9)$$

### 4.5 Memory-Augmented Deep Autoencoder for Unsupervised Anomaly Detection (Mem-AE) Gong et al. (2019):

This work challenges the second assumption behind using AEs. It shows that some abnormal samples could be perfectly reconstructed even when there are not any of them in the training dataset. Intuitively, AEs

**Input** : Set of training data  $x$ , iteration size  $N$ , parameter  $\lambda$   
**Output**: Models:  $En, De, C, D_l, D_v$

**for iteration 1 to  $\rightarrow N$  do**  
*Classifier update: keep  $D_l, D_v, En, De$  fixed.*  
 $n \leftarrow \mathcal{N}(0, I)$   
 $l_1 \leftarrow En(x + n)$   
 $l_2 \leftarrow \mathcal{U}(-1, 1)$   
 $l_{classifier} \leftarrow C(De(l_2), 0) + C(De(l_1), 1)$   
*Back-propagate  $l_{classifier}$  to change  $C$*   
*Discriminator update:*  
 $l_{latent} \leftarrow D_l(l_1, 0) + D_l(l_2, 1)$   
 $l_{visual} \leftarrow D_v(De(l_2), 0) + D_v(x, 1)$   
*Back-propagate  $l_{latent} + l_{visual}$  and change  $D_l, D_v$*   
*Informative-negative mining : Keep all networks fixed.*  
**for sub-iteration 1 to  $\rightarrow 5$  do**  
 $l_{classifier} \leftarrow C(De(l_2), 1)$   
*Back-propagate  $l_{classifier}$  to change  $l_2$*   
**end**  
*Generator update: keep  $D_l, D_v, C$  fixed.*  
 $l_{latent} \leftarrow D_l(l_1, 1) + D_l(l_2, 0)$   
 $l_{visual} \leftarrow D_v(De(l_2), 1) + D_v(x, 0)$   
 $l_{mse} \leftarrow \|x - De(l_1)\|^2$   
*Back-propagate  $l_{latent} + l_{visual} + \lambda l_{mse}$  to change  $En, De$*   
**end**

Figure 5: The training process of OC-GAN method Perera et al. (2019).

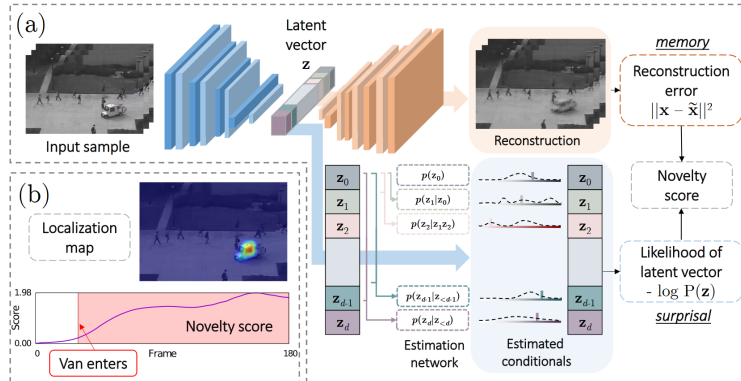

Figure 6: An overview of the LSA method is shown. A surprise score is defined based on the probability distribution of embeddings. The probability distribution is learned using an auto-regressive model. Also, reconstruction error is simultaneously optimized on normal training samples.

may not learn to extract uniquely describing features of normal samples; as a result, they may extract some abnormal features from abnormal inputs and reconstruct them perfectly. This motivates the need for learning features that allow only normal samples to be reconstructed accurately. To do so, Mem-AE employs a memory that stores unique and sufficient features of normal training samples. During training, the encoder *implicitly* plays the role of a *memory address generator*. The encoder produces an embedding, and memory features that are similar to the generated embedding are combined. The combined embedding is then passed to a decoder to make the corresponding reconstructed output. Also, Mem-AE uses a sparse addressing technique that uses only a small number of memory items. Accordingly, the decoder in Mem-AE is restricted to performing the reconstruction using a small number of addressed memory items, rendering the requirement for efficient utilization of the memory items. Furthermore, the reconstruction error forces the memory to record prototypical patterns that are representative of the normal inputs. To summarize the training process, Mem-AE (1) finds address  $Enc(x) = z$  from the encoder’s output; (2) measures the cosine

similarity  $d(z, m_i)$  of the encoder output  $z$  with each of the memory elements  $m_i$ ; (3) computes attention weights  $\mathbf{w}$ , where each of its elements is computed as follows:

$$w_i = \frac{\exp(d(z, m_i))}{\sum_{j=1}^N \exp(d(z, m_j))}; \quad (10)$$

(4) applies address shrinkage techniques to ensure sparsity:

$$\hat{w}_i = \frac{\max(w_i - \lambda, 0) \cdot w_i}{|w_i - \lambda| + \epsilon} \quad (11)$$

$$E(\hat{\mathbf{w}}^t) = \sum_{i=1}^T -\hat{w}_i \cdot \log(\hat{w}_i), \quad (12)$$

and finally, the loss function is defined as (13), where  $R$  is the reconstruction error and is used as the test time anomaly score. Fig. 7 shows the overview of architecture.

$$L(\theta_e, \theta_d, M) = \frac{1}{T} \sum_{t=1}^T (R(\mathbf{x}^t, \hat{\mathbf{x}}^t) + \alpha E(\hat{\mathbf{w}}^t)) \quad (13)$$

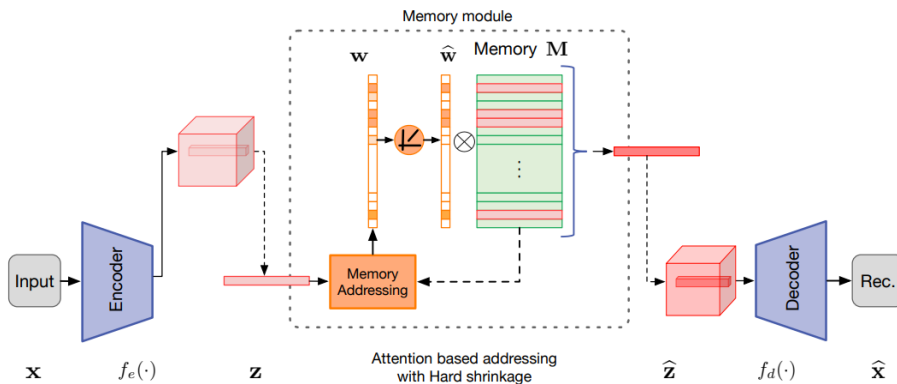

Figure 7: An overview of the Mem-AE method is shown. Each sample is passed through the encoder, and a latent embedding  $z$  is extracted. Then using the cosine similarity, some nearest learned normal features are selected from the memory, and the embedding  $\hat{z}$  is made out of them using a weighted averaging. At last, the reconstruction error of the decoded  $\hat{z}$  and input  $x$  is considered as the novelty score.

#### 4.6 Redefining the Adversarially Learned One-Class Classifier Training Paradigm (Old-is-Gold) Zaheer et al. (2020):

This work extends the idea of ALOCC Sabokrou et al. (2018a). As ALOCC is trained in a GAN-based setting, it suffers from stability and convergence issues. On one hand, the over-training of ALOCC can confuse the discriminator  $D$  because of the realistically generated fake data. On the other hand, under-training detracts the usability of discriminator features. To address this issue, a two-phase training process is proposed. In the first phase, a similar training process as ALOCC is followed :

$$\mathcal{L} = \mathcal{L}_{\mathcal{R}+D} + \mathcal{L}_{\mathcal{R}} \quad (14)$$

As phase one progresses, a low-epoch generator model  $\mathcal{G}^{\text{old}}$  for later use in phase two of the training is saved. The sensitivity of the training process to the variations of the selected epoch is discussed in the paper.

During the second phase, samples  $\hat{X} = \mathcal{G}$  are considered high-quality reconstructed data. Samples  $\hat{X}^{\text{low}} = \mathcal{G}^{\text{old}}(X)$  are considered as low-quality samples. Then, pseudo anomaly samples are created as follows:

$$\begin{aligned}\hat{X} &= \frac{\mathcal{G}^{\text{old}}(X_i) + \mathcal{G}^{\text{old}}(X_j)}{2} \\ \hat{X}^{\text{pseudo}} &= \mathcal{G}(\hat{X})\end{aligned}\tag{15}$$

After that, the discriminator is trained again to strengthen its features by distinguishing between good quality samples such as  $\{X, \hat{X}\}$  and low-quality or pseudo anomaly ones such as  $\{\hat{X}^{\text{low}}, \hat{X}^{\text{pseudo}}\}$  as follows:

$$\begin{aligned}\max_{\mathcal{D}} & \left( \alpha \cdot \mathbb{E}_X [\log(1 - D(X))] + (1 - \alpha) \cdot \mathbb{E}_{\hat{X}} [\log(1 - D(\hat{X}))] \right. \\ & + (\beta \cdot \mathbb{E}_{\hat{X}^{\text{low}}} [\log(1 - D(\hat{X}^{\text{low}}))] \\ & \left. + (1 - \beta) \cdot \mathbb{E}_{\hat{X}^{\text{pseudo}}} [\log(1 - D(\hat{X}^{\text{pseudo}}))] \right)\end{aligned}\tag{16}$$

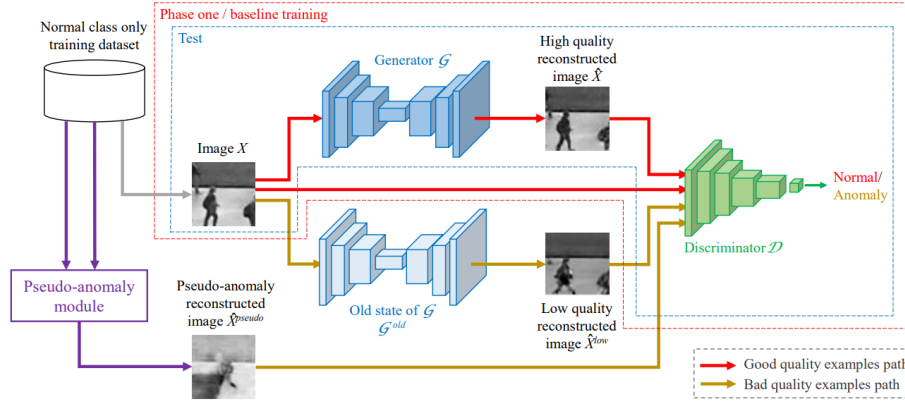

Figure 8: An overview of the Old-Is-Gold method is shown. The architecture is similar to ALOCC; however, it saves the weights of the network  $G$  during the training process, which are called  $G^{\text{old}}$ . Then,  $G^{\text{old}}$  is employed to make some low-quality samples that the discriminator is expected to distinguish as normal. Also, some pseudo abnormal samples are generated by averaging each pair of normal low-quality samples, which the discriminator is supposed to distinguish as fake inputs. This makes the discriminator’s features rich and stables the training process.

In this way,  $D$  does not collapse similar to ALOCC, and  $\mathcal{D}(\mathcal{G}(X))$  is used as the test time criterion. Fig. 8 shows the overall architecture of this method.

#### 4.7 Adversarial Mirrored Autoencoder (AMA) Somepalli et al. (2020):

The overall architecture of AMA is similar to ALOCC. However, it challenges the first assumption of AEs. It has been shown that  $l_p$  norms are not suitable for training AEs in the anomaly detection domain since they cause blurry reconstructions and subsequently increase the error of normal samples. To address this problem, AMA proposes to minimize the Wasserstein distance between distributions  $\mathbb{P}_{X,X}$  and  $\mathbb{P}_{X,\hat{X}}$ . The objective function is as follows:

$$W(\mathbb{P}_{X,X}, \mathbb{P}_{X,\hat{X}}) = \max_{D \in Lip-1} \mathbb{E}_{x \sim \mathbb{P}_X} [\mathcal{D}(X, X) - \mathcal{D}(X, \hat{X})] \quad (17)$$

where  $\hat{X}$  is the reconstructed image.

Berthelot et al. (2018) showed that by forcing the linear combination of latent codes of a pair of data points to look realistic after decoding, the encoder learns a better representation of data. Inspired by this, AMA makes use of  $\hat{X}_{\text{inter}}$ —obtained by decoding the linear combination of some randomly sampled inputs:

$$\min_G \max_{D \in Lip-1} \mathbb{E}_{x \sim \mathbb{P}_X} [\mathcal{D}(X, X) - \mathcal{D}(X, \hat{X}_{\text{inter}})] \quad (18)$$

To further boost discriminative abilities of  $D$ , inspired by Choi & Jang (2018) proposing normal samples reside in the typical set Cover & Thomas (2006) while anomalies reside outside of it, a Gaussian regularization equal to  $L_2$  norm is imposed on the latent representation. Then using the Gaussian Annulus Theorem Vershynin (2018) stating in a  $d$ -dimensional space, the typical set resides with high probability at a distance of  $\sqrt{d}$  from the origin, synthetic negatives (anomalies), are obtained by sampling the latent space outside and closer to the typical set boundaries. Therefore, the final objective function is defined as follows:

$$\begin{aligned} & \min_G \max_{D \in Lip-1} \mathcal{L}_{\text{normal}} - \lambda_{\text{neg}} \cdot \mathcal{L}_{\text{neg}} \\ & \mathcal{L}_{\text{normal}} = \mathbb{E}_{x \sim \mathbb{P}_X} \left[ D(X, X) - D(X, \hat{X}) \right. \\ & \quad \left. + \lambda_{\text{inter}} \cdot (D(X, X) - D(X, \hat{X}_{\text{inter}})) + \lambda_{\text{reg}} \cdot \|E(X)\| \right] \\ & \mathcal{L}_{\text{neg}} = \mathbb{E}_{x \sim \tilde{\mathbb{Q}}_X} \left[ D(X, X) - D(X, \hat{X}_{\text{neg}}) \right] \end{aligned} \quad (19)$$

Fig. 9 shows an overview of the method and the test time criterion is  $\|f(X, X) - f(X, G(E(X)))\|_1$  where  $f$  is the penultimate layer of  $D$ .

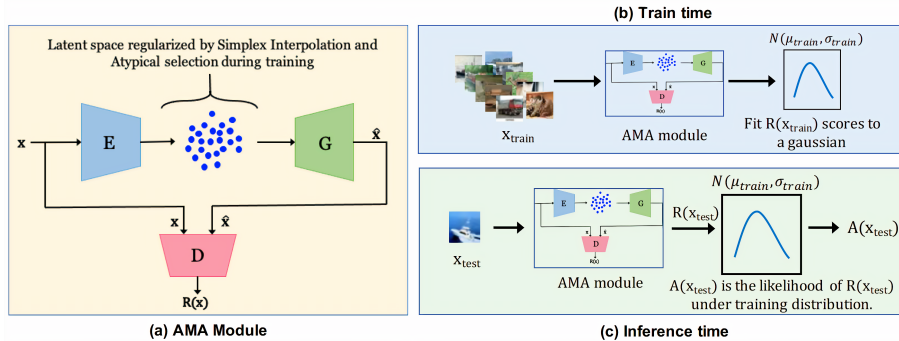

Figure 9: An overview of AMA method is shown. The architecture is similar to ALOCC; however, it does not try to minimize reconstruction error between  $x$  and  $\hat{x}$ . Instead, a discriminator is trained with Wasserstein Loss to minimize the distance between the distribution  $(x, x)$  and  $(x, \hat{x})$ . In this way, it forces  $\hat{x}$  to be similar to  $x$  without using any  $l_p$  norm that causes blurred reconstructed outputs. Moreover, some negative latent vectors are sampled from low probability areas, which the discriminator is supposed to distinguish as fake ones. This makes the latent space consistent compared to the previous similar approaches.

#### 4.8 Unsupervised Anomaly Detection with Generative Adversarial Networks to Guide Marker Discovery (AnoGAN) Schlegl et al. (2017):

This work trains a GAN on normal training samples, then at the test time, solves an optimization problem that attempts to find the best latent space  $z$  by minimizing a discrepancy. The discrepancy is found by using

a pixel-level loss of the generated image and input in combination with the loss of discriminator’s features at different layers when the generated and input images are fed. Intuitively, for normal test time samples, a desired latent vector can be found despite abnormal ones. Fig. 10 shows the structure of the method.

As inferring the desired latent vector through solving an optimization problem is time-consuming, some extensions of AnoGAN have been proposed. For instance, Efficient-GAN Zenati et al. (2018) tries to substitute the optimization problem by training an encoder  $E$  such that the latent vectors  $z'$  approximate the distribution of  $z$ . In this way,  $E$  is used to produce the desired latent vector, significantly improving test time speed. Fig. 11 shows differences. The following optimization problem (20) is solved at the test time to find  $z$ . The anomaly score is assigned based on how well the found latent vector can minimize the objective function.

$$\min_z (1 - \lambda) \cdot \sum |x - G(z)| + \lambda \cdot \sum |D(x) - D(G(z))| \tag{20}$$

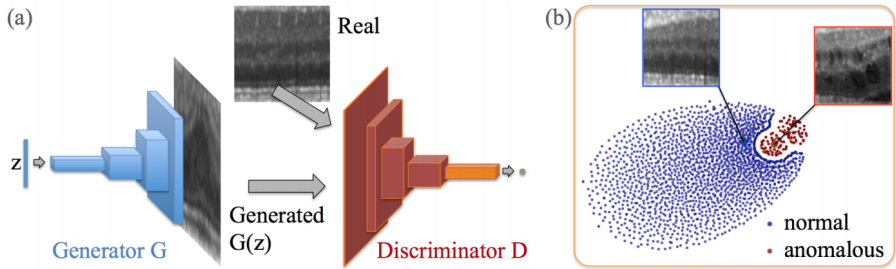

Figure 10: An overview of AnoGAN method. At first, a generator network  $G$  and a discriminator  $D$  are trained jointly on normal training samples using the standard training loss, which yields a semantic latent representation space. Then at the test time, an optimization problem that seeks to find an optimal latent embedding  $z$  that mimics the pixel-level and semantic-level information of the input is solved. Intuitively, for normal samples, a good approximation of inputs can be found in the latent space; however, it is not approximated well for abnormal inputs.

Figure 11: Figure A shows the architecture of AnoGAN. Figure B shows the architecture of Efficient-GAN. The encoder  $E$  mimics the distribution of the latent variable  $z$ . The discriminator  $D$  learns to distinguish between joint distribution of  $(x, z)$  instead of  $x$ .

#### 4.9 Deep One-Class Classification (DeepSVDD) Ruff et al. (2018):

This method can be seen as an extension of SVDD using a deep network. It assumes the existence of shared features between training samples, and tries to find a latent space in which training samples can be compressed into a minimum volume hyper-sphere surrounding them. Fig. 12 shows the overall architecture. The difference *w.r.t* traditional methods is the automatic learning of kernel function  $\phi$  by optimizing the parameters  $W$ . To find the center  $c$  of the hyper-sphere, an AE is first trained on the normal training samples, then the average of normal sample latent embeddings is considered  $c$ . After that, by discarding the decoder part, the encoder is trained using the following objective function:

$$\min_W \frac{1}{n} \sum_{i=1}^n \|\phi(x_i; W) - c\|_2^2 + \frac{\lambda}{2} \sum_{l=1}^L \|W^l\|_F^2, \quad (21)$$

where  $W^l$  shows the weights of encoder's  $l$ th layer. At the test time, anomaly score is computed based on  $\|\phi(x; W^*) - c\|_2^2$  where  $W^*$  denotes trained parameters.

Figure 12: An overview of the DSVDD method is shown. It finds a minimum volume hyper-sphere that contains all training samples. As the minimum radius is found, more distance to the center is expected for abnormal samples compared to normal ones.

#### 4.10 Deep Semi-Supervised Anomaly Detection Ruff et al. (2019):

This is the semi-supervised version of DSVDD which assumes a limited number of labeled abnormal samples. The loss function is defined to minimize the distance of normal samples from a pre-defined center of a hyper-sphere while maximizing abnormal sample distances. The objective function is defined as follows:

$$\begin{aligned} \min_W & \frac{1}{n+m} \sum_{i=1}^n \|\phi(x_i; W) - c\|_2^2 + \\ & \frac{\eta}{n+m} \sum_{j=1}^m (\|\phi(\hat{x}_j; W) - c\|_2^2)^{\hat{y}_j} + \frac{\lambda}{2} \sum_{l=1}^L \|W^l\|_F^2 \end{aligned} \quad (22)$$

Note that, as mentioned above, there is access to  $(\hat{x}_1, \hat{y}_1), \dots, (\hat{x}_m, \hat{y}_m) \in X \times Y$  with  $Y = \{-1, +1\}$  where  $\hat{y} = 1$  denotes known normal samples and  $\hat{y} = -1$  otherwise.  $c$  is specified completely similar to DSVDD by averaging on the latent embeddings of an AE trained on normal training samples. From a bit theoretical point of view, AE's objective loss function helps encoder maximizes  $I(X; Z)$  that  $X$  denotes input variables and  $Z$  denotes latent variables. Then, it can be shown that (22) minimizes the entropy of normal sample latent embeddings while maximizing it for abnormal ones as follows:

$$\begin{aligned}
H(Z) &= E[-\log(P(Z))] = - \int_Z p(z) \log p(z) dz \\
&\leq \frac{1}{2} \log((2\pi e)^d \det(\Sigma)) \propto \log \sigma^2
\end{aligned} \tag{23}$$

As the method makes normal samples compact, it forces them to have low variance, and consequently, their entropy is minimized. The final theoretical formulation is approximated as follows:

$$\max_{p(z|x)} I(X; Z) + \beta(H(Z^-) - H(Z^+)) \tag{24}$$

#### 4.11 Deep Anomaly Detection Using Geometric Transformations (GT) Golan & El-Yaniv (2018):

GT attempts to reformulate the one-class classification problem into a multi-class classification. GT defines a set of transformations that do not change the data distribution, then trains a classifier to distinguish between them. Essentially, the classifier is trained in a self-supervised manner. Finally, a Dirichlet distribution is trained on the confidence layer of the classifier to model non-linear boundaries. Abnormal samples are expected to be in low-density areas since the network can not confidently estimate the correct transformation. At the test time, different transformations are applied to the input, and the sum of their corresponding Dirichlet probabilities is assigned as the novelty score. An overview of the method is shown in Fig. 13.

Figure 13: An overview of the GT method is shown. A set of transformations is defined, then a classifier must distinguish between them. Having trained the classifier in a self-supervised manner, a Dirichlet distribution is trained on the confidence layer to model their boundaries.

#### 4.12 Effective End-To-End Unsupervised Outlier Detection via Inlier Priority of Discriminative Network Wang et al. (2019):

In this work, similar to GT, a self-supervised learning (SSL) task is employed to train an anomaly detector except in the presence of a minority of outliers or abnormal samples in the training dataset. Suppose the following training loss is used as the objective function:

$$L_{SS}(x_i | \theta) = -\frac{1}{K} \sum_{y=1}^K \log(P^{(y)}(x_i^{(y)} | \theta)), \tag{25}$$

where  $x_i^{(y)}$  is obtained by applying a set of transformations  $O(\cdot | y)$ , and  $y$  indicates each transformation. The anomaly detection is obtained based on the objective function score. We take the rotation prediction task

as an example. During training, the classifier learns to predict the amount of rotation for normal samples. During test time, different rotations are applied on inputs, the objective function scores for normal samples would be lower than abnormal ones.

However, due to the presence of abnormal samples in the training dataset, the objective score for abnormal samples may not always be higher. To address this issue, it is shown that the magnitude and direction of gradient in each step have a significant tendency toward minimizing inlier samples' loss function. Thus the network produces lower scores compare to abnormal ones. Wang et al. (2019) exploits the magnitude of transformed inliers and outliers' aggregated gradient to update  $w_c$ , i.e.  $\|\nabla_{w_c}^{(\text{in})} L\|$  and  $\|\nabla_{w_c}^{(\text{out})} L\|$ , which are shown to follow this approximation:

$$\frac{E(\|\nabla_{w_c}^{(\text{in})} \cdot L\|^2)}{E(\|\nabla_{w_c}^{(\text{out})} \cdot L\|^2)} \approx \frac{N_{\text{in}}^2}{N_{\text{out}}^2} \quad (26)$$

where  $E(\cdot)$  denotes the probability expectation. As  $N_{\text{in}} \gg N_{\text{out}}$ , normal samples have more effect on the training procedure. Also, by projecting and averaging the gradient in the direction of each of the training sample's gradient  $(-\nabla_{\theta} L(x) \cdot \frac{-\nabla_{\theta} L(x_i)}{\|-\nabla_{\theta} L(x_i)\|})$ , the stronger effect of inlier distribution vs outlier one is observed again. Fig. 14 shows the effect empirically.

Figure 14: The average magnitude of the gradient for inliers and outliers with respect to the number of iterations. The class used as inliers is in brackets.

#### 4.13 Classification-Based Anomaly Detection for General Data (GOAD) Bergman & Hoshen (2020):

This work is very similar to GT. It trains a network to classify between different transformations; however, instead of using cross-entropy loss or training a Dirichlet distribution on the final confidences, it finds a center for each transformation and minimizes the distance of each transformed data with its corresponding center as follows :

$$P(m' | T(x, m)) = \frac{e^{-\|f(T(x, m)) - c_{m'}\|^2}}{\sum_{\hat{m}} e^{-\|f(T(x, m)) - c_{\hat{m}}\|^2}} \quad (27)$$

where the centers  $c_m$  are given by the average feature over the training set for every transformation i.e.  $c_m = \frac{1}{N} \sum_{x \in X} f(T(x, m))$ . For training  $f$ , two options are used. The first one is using a simple cross entropy on  $P(m' | T(x, m))$  values, and the second one is using the center triplet loss He et al. (2018) as follows:

$$\sum_i \max(0, \|f(T(x_i, m)) - c_m\|^2 + s - \min_{m' \neq m} \|f(T(x_i, m)) - c_{m'}\|^2) \quad (28)$$

where  $s$  is a margin regularizing the distance between clusters.

The idea can be seen as the combination of DSVDD and GT in which GT’s transformations are used, and different compressed hyperspheres are learned to separate them.  $M$  different transformations transform each sample at the test time, and the average of correct label probabilities is assigned as the anomaly score.

#### 4.14 CSI: Novelty Detection via Contrastive Learning on Distributionally Shifted Instances Tack et al. (2020):

This work attempts to formulate the problem of novelty detection into a contrastive framework similar to SimCLR Chen et al. (2020b). The idea of contrastive learning is to learn an encoder  $f_\theta$  to extract the necessary information to distinguish similar samples from the others. Let  $x$  be a query,  $x_+$ , and  $x_-$  be a set of positive and negative samples respectively,  $z$  be the encoder’s output feature or the output of an additional projection layer  $g_\phi(f_\theta(x))$  for each input, and suppose  $\text{sim}(z, z')$  is cosine similarity. Then, the primitive form of the contrastive loss is defined as follows:

$$L_{\text{con}}(x, x_+, x_-) := -\frac{1}{|x_+|} \log \frac{\sum_{x' \in x_+} e^{\text{sim}(z(x), z(x'))/\tau}}{\sum_{x' \in x_+ \cup x_-} e^{\text{sim}(z(x), z(x'))/\tau}} \quad (29)$$

Specifically for SimCLR, the contrastive loss above is converted into the formulation below:

$$L_{\text{SimCLR}}(B; T) := \frac{1}{2B} \sum_{i=1}^B L_{\text{con}}(\hat{x}_i^{(1)}, \hat{x}_i^{(2)}, \hat{B}_{-i}) + L_{\text{con}}(\hat{x}_i^{(2)}, \hat{x}_i^{(1)}, \hat{B}_{-i}) \quad (30)$$

where  $(\hat{x}_i^{(1)}, \hat{x}_i^{(2)}) = (T_1(x_i), T_2(x_i))$  for the transformations  $T_1$  and  $T_2$  from a set of transformations  $T$ ,  $B := \{x_i\}_{i=1}^B$ , and  $\hat{B}_{-i} := \{\hat{x}_j^{(1)}\}_{j \neq i} \cup \{\hat{x}_j^{(2)}\}_{j \neq i}$ .

However, contrastive learning requires defining a set of negative samples. To this end, a collection of transformations that shift the distribution of training samples ( $S$ ) is specified to make the desired negative set when applied on each input. For instance, rotation or patch permutation completely shifts the original input samples’ distribution; therefore, they can be used as negative samples. Also, another set of transformations called align transformations ( $T$ ) is defined as not changing the distribution of training images as much as ( $S$ ). Then the *Contrasting shifted instances* (CSI) loss can be defined as follows:

$$L_{\text{con-SI}} := L_{\text{SimCLR}}(\cup_{s \in S} B_s; T) \quad (31)$$

where  $B_s := \{s(x_i)\}_{i=1}^B$ . Here, CSI regards each distributionally-shifted sample as an OOD with respect to the original sample. The goal is to discriminate an in-distribution sample from other OOD i.e., ( $s \in S$ ) samples.

Further, to facilitate  $f_\theta$  to discriminate each shifted instance, a classification loss for classifying shifted instances is defined in combination with  $L_{\text{con-SI}}$ . To do so, a linear layer for modeling an auxiliary softmax classifier  $p_{\text{cls-SI}}(y^S | x)$  is added to  $f_\theta$  as in GT or GOAD:

$$L_{\text{cls-SI}} = \frac{1}{2B} \frac{1}{K} \sum_{s \in S} \sum_{\hat{x}_s \in B_s} -\log p_{\text{cls-SI}}(y^s = s | \hat{x}_s), \quad (32)$$

where  $\hat{B}_s$  is the batch augmented from  $B_s$ . In testing, the cosine similarity to the nearest training sample in  $\{x_m\}$  multiplied by the norm of representation  $\|z(x)\|$  is used. The contrastive loss increases the norm of in-distribution samples, as it is an easy way to minimize the cosine similarity of identical samples by increasing the denominator of (29). To further improve the scoring criterion, ensembling over random augmentations or utilizing shifting transformations similar to GOAD can be employed.

#### 4.15 DA-Contrastive: Learning and Evaluating Representations for Deep One-class Classification Sohn et al. (2020): (R1)

This research tries to put the problem of novelty detection into a contrastive framework, similar to the other methods mentioned previously in Tack et al. (2020) and Golan & El-Yaniv (2018). Tack et al. (2020) investigates that all of the augmentations that are utilized in the contrastive loss presented at 29 are not necessarily effective for the one-class learning. As a result, rotated versions of the input are treated as separate distributions in this study, and are accounted as negative samples in the contrastive loss. Positive samples are also created by applying augmentations to each distribution, such as color jittering. Finally, the one-class classifier are trained on the positive and negative samples in a contrastive learning manner. After that, a KDE or OC-SVM Schölkopf et al. (1999) is trained on the learned representation of normal training samples, which is used at the test time. An overview of the method can be seen in Fig. 15.

Figure 15: An overview of the DA-Contrastive method is represented. This work trains a one-class classifier employing a novel variant of contrastive learning with distribution augmentations such that the class collision between examples from the same class is reduced. This implies discriminating different distributions generated by augmentations of different rotations from the original input (see the right side), which results in less uniformity and more compactness in the feature space (see the left side).

#### 4.16 Uninformed Students: Student-Teacher Anomaly Detection With Discriminative Latent Embeddings Bergmann et al. (2020):

This work trains a teacher network using metric learning and knowledge distillation techniques to provide a semantic and discriminative feature space. The teacher  $T$  is obtained by first training a network  $\hat{T}$  that embeds patch-sized images  $p$  into a metric space. Then, fast dense local feature extraction for an entire input image can be achieved by a deterministic network transformation from  $\hat{T}$  to  $T$ , as described in Bailer et al. (2018). To train  $\hat{T}$ , a large number of training patches  $p$  are obtained by randomly cropping an image database, for instance, ImageNet. Then using the following knowledge distillation loss, the knowledge of a pre-trained network  $P$  is distilled into  $\hat{T}$  as follows:

$$L_k(\hat{T}) = \|D(\hat{T}(p)) - P(p)\|^2, \quad (33)$$

where  $D$  is used to align the size of output spaces. This helps the use of computationally efficient network  $\hat{T}$  instead of  $P$  at the test time while the required knowledge is distilled.

To further enrich the feature space of  $\hat{T}$ , an SSL method is employed such that the feature space of patches that are obtained by applying small translations, small changes in the image luminance, and the addition of Gaussian noise to  $p$  be similar. This set is called  $p^+$  as opposed to  $p^-$ , which is obtained using random cropping regardless of the neighborhood to the patch  $p$ . The SSL loss is defined as follows:

$$\begin{aligned} \delta^+ &= \|\hat{T}(p) - \hat{T}(p^+)\|^2 \\ \delta^- &= \min\{\|\hat{T}(p) - \hat{T}(p^-)\|^2, \|\hat{T}(p^+) - \hat{T}(p^-)\|^2\} \\ L_m(\hat{T}) &= \max\{0, \delta + \delta^+ - \delta^-\} \end{aligned} \quad (34)$$

where  $\delta > 0$  denotes the margin parameter. Finally, to reduce the redundancy of feature maps of  $\hat{T}$ , a compactness loss which minimizes their cross-correlation is used as follows:

$$L_c(\hat{T}) = \sum_{i \neq j} c_{ij} \quad (35)$$

therefore, the final loss is  $L_c(\hat{T}) + L_m(\hat{T}) + L_k(\hat{T})$ .

Having a teacher  $T$  trained comprehensively to produce a  $d$  dimensional feature maps for each pixel of an input image, an ensemble of student networks is forced to approximate the feature maps of  $T$  for each pixel locating at the row  $r$  and column  $c$  as follows:

$$L(S_i) = \frac{1}{wh} \sum_{(r,c)} \|\mu_{(r,c)}^{S_i} - (y_{(r,c)}^T - \mu) \text{diag}(\sigma)^{-1}\|_2^2 \quad (36)$$

where  $\mu$  and  $\sigma$  are used for data normalization, note that the receptive field of each student is limited to a local image region  $p_{(r,c)}$ , this helps the students to obtain dense predictions for each image pixel with only a single forward pass without having actually to crop the patches  $p_{(r,c)}$ . At the test time, as students have only learned to follow their teacher on normal training samples, their average ensemble error can be used to detect abnormal samples. Intuitively, they wouldn't follow their teacher on abnormal samples and produce a high average error.

#### 4.17 Self-Supervised Learning for Anomaly Detection and Localization (CutPaste) Li et al. (2021):

This work designs a simple SSL task that to capture local, pixel-level regularities instead of global, semantic-level ones. While GT or GOAD utilize transformations such as rotation, translation, or jittering, CutPaste cuts a patch of its training input and copies it in another location. The network is trained to distinguish between defected samples and intact ones. Extra auxiliary tasks such as cutout and Scar can be used in combination with the cut-paste operation. After training, a KDE or Gaussian density estimator is trained on the confidence scores of normal training samples, which is used at the test time. Due to the simplicity of the method, it may overfit easily on the classification task. However; several experiments in the paper show contrary to this assumption. An overview of the method can be seen in Fig. 16.

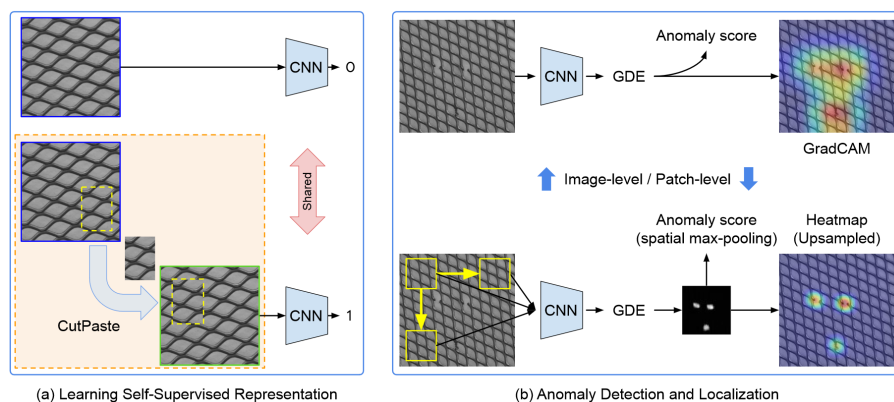

Figure 16: An overview of CutPaste. A network is trained to classify artificially made defected samples from the original ones. Despite the simplicity of the method, it does not overfit on MVTEC-AD dataset.

#### 4.18 Multiresolution Knowledge Distillation for Anomaly Detection (Multi-KD) Salehi et al. (2021b):

Generative models are suited for detecting pixel-level anomalies; however, they may fail on complex, semantic-level ones. In contrast, discriminative models are good at capturing semantics. Designing an

SSL task that captures both semantic and syntax is not easy. To address this issue, Multi-KD attempts to mimic the intermediate layers of a VGG pre-trained network—called intermediate knowledge—into a simpler network using knowledge distillation. This way, multi-resolution modeling of the normal training distribution is obtained and can be used to detect both pixel-level and semantic-level anomalies at the test time. Here, the concept of knowledge is defined to be the length and direction of a pre-trained network on ImageNet Deng et al. (2009). A cloner network has a simple yet similar overall architecture compared to the source, making its knowledge similar to the source on normal training samples. At the test time, the cloner can follow the source on the normal test time samples; however, it fails for the abnormal ones. This results in a high discrepancy that can be used at the test time. Fig. 17 shows the overall architecture.

Similar methods exist, which model the distribution of different layers of a pre-trained network using multi-variate Gaussian descriptors such as PaDiM Defard et al. (2020) or Rippel et al. (2021). An overview of the architecture of Rippel et al. (2021) is shown in the Fig. 18.

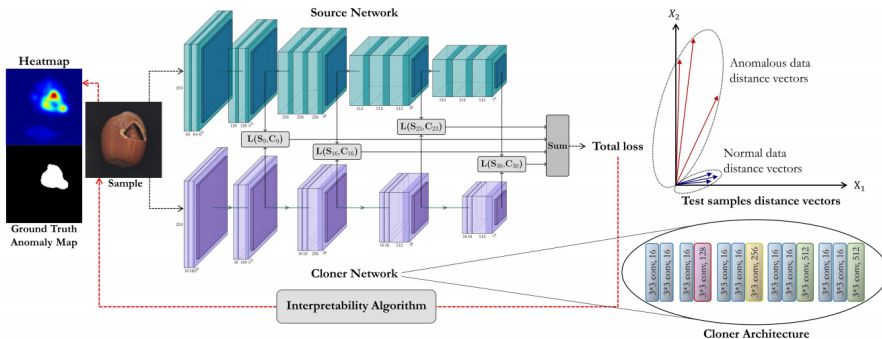

Figure 17: An overview of the Multi-KD method is shown. It distills multi-resolution knowledge of a pre-trained source network on the normal training distribution into a simpler cloner one. The structure of source and cloner is similar to each other. Therefore, the cloner distills the source’s knowledge in the corresponding layers. At the test time, their discrepancy would be low for normal inputs despite abnormal ones.

### 5 Open-set Recognition

Open-set recognition (OSR) receives more supervision than AD or ND. In this setting,  $K$  normal classes are given at the training time. In testing,  $N$  classes with  $N - K$  unknown and  $K$  known classes exist. The objective is to identify unknown classes while classifying the known ones. It has a lot of applications in which labeling normal dataset is more feasible, or gathering a cleaned dataset without having any abnormal sample is possible. As there is more supervision, training data can be categorized into four classes:

- *known known classes (KKC)*: Training samples that we know they are known. They are already given and labeled.
- *known unknown classes (KUC)*: Training samples that we know they are not known. This means, they do not belong to the known categories. For example, background images, or any image that we know is not categorized into the known classes are in this group. They are already given and labeled.
- *unknown known classes (UKC)*: Training samples that we do not know they are known. For example, known test time samples are in this group. These are not given at the training phase.
- *unknown unknown classes (UUC)*: Training samples that we do not know they are not known. For example, unknown test time samples are in this group. These are not given at the training phase.

The space that is far from known classes, including KKC and KUC, is called **open space** OScheirer et al. (2012). Labeling any sample in this space has a risk value denoted by  $R_O$ . The risk factor is usually

Figure 18: An overview of Rippel et al. (2021). It models the different layers’ distribution of a pre-trained network using Gaussian descriptors. Then, at the test time, the probability of being normal is computed using the training time means and variances.

represented as Eq. 37 in which  $S_o$  is the overall measuring space, and  $f$  is the measurable recognition (classification) function Scheirer et al. (2012). The value of  $f$  is 1 if the input belongs to KKC otherwise 0.

$$R_O(f) = \frac{\int_O f(x) dx}{\int_{S_o} f(x) dx} \tag{37}$$

As discussed in Geng et al. (2020), there are some difficulties in defining the practical formulation of openness; therefore, we use the definition of Geng et al. (2020) as in Eq. 38, where  $C_{TR}$  is the set of classes used in training, and  $C_{TE}$  is the set of classes used in the testing.

$$O = 1 - \sqrt{\frac{2 \times |C_{TR}|}{|C_{TR}| + |C_{TE}|}} \tag{38}$$

Larger values of  $O$  correspond to more open problems, and 0 is assigned to a completely closed one. OSR problem can be defined as finding recognition functions  $f$  in such a way that it minimizes the risk factor  $R_O$ .

**5.1 Towards Open Set Deep Networks (OpenMax) Bendale & Boulton (2016):**

This work addresses the problem that classification models produce overconfident scores for unseen test time samples. Due to the normalization in softmax computation, two samples with completely different logit scores may have the same confidence score distribution. Instead of using the confidence score, OpenMax resorts to the logit scores that are shown by *Activation Vector* (AV). AV of each sample captures the distribution over classes. The mean AV (MAV) is defined to be the average of AV values across all samples. As for each input sample, the value in AV corresponding to the ground truth is supposed to be high; its distance to

the corresponding value of MAV would be high too. Considering the distance of each element in AVs from the corresponding element in MAV as a random variable, correctly classified inputs would have the highest distances for ground truth elements. This might happen for a few classes that are not ground truth while having a strong relationship with ground truth. For instance, the class `leopard` as the ground truth and `cheetah` as a near class. To model the distribution of these highest values, the Extreme Value Theorem (EVT) can be used as follows:

EVT : Let  $(s_1, s_2, \dots, s_n)$  be a sequence of i.i.d samples. Let  $M_n = \max(s_1, \dots, s_n)$ . If a sequence of pairs of real numbers  $(a_n, b_n)$  exists such that each  $0 \leq a_n$  and

$$\lim_{n \rightarrow \infty} P\left(\frac{M_n - b_n}{a_n} \leq x\right) = F(x) \quad (39)$$

Then if  $F$  is non-degenerate distribution function, it belongs to one of three extreme value distributions Pickands III et al. (1975). For this work, it is Weibull distribution. By modeling the distribution of extremes for each class, one can easily compute the probability of each test input being an extreme and discard remaining ones.

In summary, during training, the CDF of extreme values for each class or element of AVs are approximated using EVT and correctly classified training samples. For each test-time input sample, the top  $\alpha$  elements in AV are selected, representing ground truth and near classes; then, their CDFs are assigned to variables  $w_{s(i)}(x)$  as Fig. 19 shows. These probabilities represent the chance of each AV's element  $v_j(x)$  to be the maximum. After that, an arbitrary class is added to the existing ones as the representative of unknown unknown samples, let's call class 0, and all activation values are normalized as follows:

$$\begin{aligned} \hat{v}(x) &= \mathbf{v}(x) \circ w(x) \\ \hat{v}_0(x) &= \sum_i v_i(x)(1 - w_i(x)) \end{aligned} \quad (40)$$

The normalization is performed so that the activation vector of UUC would be high if  $w_{s(i)}(x)$ s are small. Finally, softmax is computed based on the normalized activation vector, and unknown or uncertain inputs are rejected. All hyper-parameters such as  $\epsilon, \alpha$  are tuned using a validation set including both seen and unseen samples.

## 5.2 Generative OpenMax for Multi-Class Open Set Classification (G-OpenMax) Ge et al. (2017):

This work is similar to OpenMax except for artificially generating UUC samples with GANs and fine-tuning OpenMax. This removes the need to have a validation dataset. To generate UUCs, a conditional GAN is trained on the KKC as follows:

$$\begin{aligned} \min_{\phi} \max_{\theta} &= \mathbb{E}_{x, c \sim P_{\text{data}}} [\log(D_{\theta}(x, c))] \\ &+ \mathbb{E}_{z \sim P_z, c \sim P_c} [\log(1 - D_{\theta}(G_{\phi}(z, c), c))] \end{aligned} \quad (41)$$

New samples are generated by interpolating the KKC's latent space. If the generated sample is not classified as one of the mixing labels, the image is considered UUC. Finally, another classifier called  $Net^G$  (see Fig. 20) is trained using both of the UUC and KKC samples such that UUCs can be assigned to the class 0 of the classifier. The inference steps are similar to OpenMax except that the normalization process for the class 0 and other classes is the same.

## 5.3 Open Set Learning with Counterfactual Images (OSRCI) Neal et al. (2018):

This work follows the idea of generating UUC samples as in G-OpenMax. A generated input is made similar to a KKC yet not to be assigned to the same class. Such generated inputs are called counter-factual

---

**Algorithm** OpenMax probability estimation with rejection of unknown or uncertain inputs.

**Require:** Activation vector for  $\mathbf{v}(\mathbf{x}) = v_1(x), \dots, v_N(x)$

**Require:** means  $\mu_j$  and libMR models  $\rho_j = (\tau_i, \lambda_i, \kappa_i)$

**Require:**  $\alpha$ , the number of “top” classes to revise

1: Let  $s(i) = \text{argsort}(v_j(x))$ ; Let  $\omega_j = 1$

2: **for**  $i = 1, \dots, \alpha$  **do**

3:  $\omega_{s(i)}(x) = 1 - \frac{\alpha-i}{\alpha} e^{-\left(\frac{\|x - \tau_{s(i)}\|}{\lambda_{s(i)}}\right)^{\kappa_{s(i)}}}$

4: **end for**

5: Revise activation vector  $\hat{v}(x) = \mathbf{v}(\mathbf{x}) \circ \omega(\mathbf{x})$

6: Define  $\hat{v}_0(x) = \sum_i v_i(x)(1 - \omega_i(x))$ .

7:

$$\hat{P}(y = j|\mathbf{x}) = \frac{e^{\hat{v}_j(\mathbf{x})}}{\sum_{i=0}^N e^{\hat{v}_i(\mathbf{x})}} \quad (42)$$

8: Let  $y^* = \text{argmax}_j P(y = j|\mathbf{x})$

9: Reject input if  $y^* = 0$  or  $P(y = y^*|\mathbf{x}) < \epsilon$

---

Figure 19: The inference algorithm of open-max. The class 0 is added in addition to other classes and considered as the unknown class; then, its probability is computed for each of the input samples, and the probabilities of top k values are normalized with respect to the unknown class’s probability. At last, if the most significant value is for class 0 or the confidence of top  $k$  values is less than a specific amount, the sample is discarded.

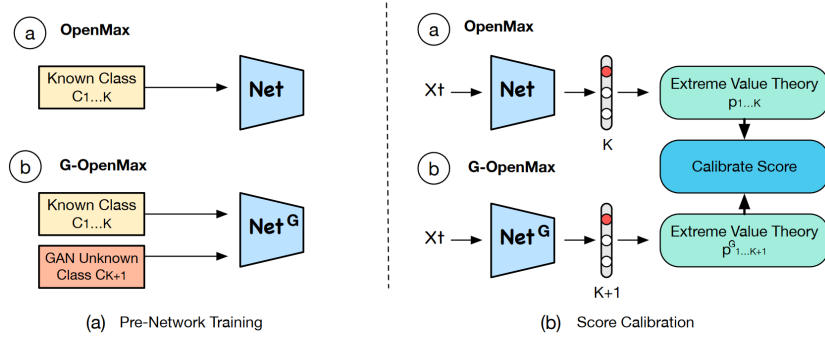

Figure 20: The overall architecture of G-OpenMax compared to the base OpenMax. As it is shown, everything is completely the same except the unknown unknown sample generation, which is done using a GAN.

examples. As these samples are near the boundary of UUCs, they can better help approximate the real UUC distribution.

Specifically, a classifier is trained on  $k$  classes. A GAN-based method such as ALOCC is trained. The discriminator is trained using a Wasserstein critic with gradient penalty as follows:

$$L_D = \sum_{x \in X} D(G(E(x))) - D(x) + P(D) \quad (42)$$

$$L_G = \sum_{x \in X} \|x - G(E(x))\|_1 - D(G(E(x))),$$

where  $P(D) = \lambda \cdot (\|\nabla_{\hat{x}} D(\hat{x}) - 1\|_2)$ . The counter-factual samples are generated by optimizing a latent vector  $z$ , which has a small distance to the latent vector of an arbitrary training sample  $x$  while its decoded image produces low confidence scores for each of the known classes:

$$z^* = \min_z \|z - E(x)\|_2^2 + \log \left( 1 + \sum_{i=1}^K e^{C_{\kappa}(G(z))^i} \right), \quad (43)$$

where  $C_K$  is the classifier and  $C_K(G(z))_i$  is the logit of the counterfactual image  $G(z)$  for class  $i$ . The generated UUCs are used in combination with KKC’s to train a new classifier  $C_{K+1}$ , which is used at the test time.

#### 5.4 Reducing Network Agnostophobia Dhamija et al. (2018):

In applications such as object detection, there is usually a class called background. On the internet, a large number of samples can be crawled, which can be used as “background” for a specific task. This work employs background samples as an auxiliary KUC distribution to train a classifier. The training facilitates KUC to have small feature magnitudes while KKC’s have larger magnitudes with a defined margin. Also, the entropy of the confidence layer is maximized for the background samples, which is equivalent to increasing the classifier’s uncertainty for such inputs. The training employs a simple entropic open-set loss that maximizes the entropy of confidence scores, along with the objectsphere loss minimizing the  $L_2$  norm of final features. Fig. 21 shows the effect of each loss on the geometric location of each class’s samples at the final layer. At the test time, the thresholding is based on  $S_c(x) \cdot \|F(x)\|$ , where  $F(x)$  is the representation from penultimate layer.

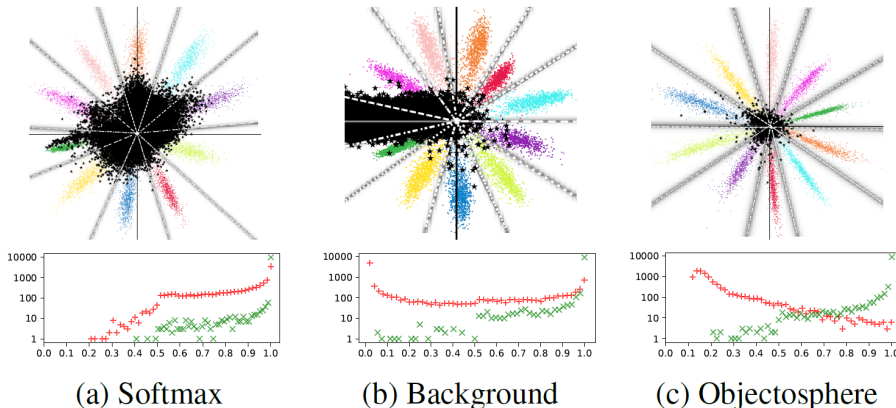

Figure 21: The effect of different loss functions on the last layer of a classifier. The classifier is trained on the MNIST dataset. The background class is considered to be NIST letters Grother & Hanaoka (2016). Black dots show samples from Devanagari Pant et al. (2012) as UUCs, and the gray lines show the boundaries of different classes. (a) shows the last layer when the network is trained only with softmax loss. (b) shows similar setting to (a); however, background samples are used as a separate class. (c) shows the last layer when the network is trained with the objectsphere loss. The figures in the bottom are histograms of softmax probability values for samples of KKC’s with green color and UUCs with the red one.

#### 5.5 Class Conditioned Auto-Encoder for Open-Set Recognition (C2AE) Oza & Patel (2019):

The second premise behind employing AEs is used in this study, which states that abnormal test time samples should not be reconstructed as well as normal ones. Nevertheless, despite AD and ND, in OSR, training labels are used to increase AE abilities. (R3) Here, an AE is used as the meta-recognition function while its encoder plays the role of a classifier for the recognition task. Intuitively, this work wants the encoder to classify each passed sample correctly and provide embeddings by which the reconstruction of the original input is possible. Furthermore, it imposes other constraints to force encoder embeddings not to be easily converted to each other, e.g., by applying linear transformations, which prevents the AE from utilizing the learned features to reconstruct abnormal/unseen inputs.

To this end, at first, the encoder that is a classifier is trained and fixed. Then for a given input  $X_i$  a match vector  $l_m = l_{y_j^m} \in \{-1, 1\}^K$  where  $K$  is the number of classes is defined such that  $l$  is equal to 1 for the  $y^j$ th element and  $-1$  otherwise. Similarly, some none-match vectors  $l_{nm} = l_{y_j^{nm}}$  for any random  $y_j^{nm} \neq y_i$  sampled randomly from labels are considered. After that, two neural networks  $H_\gamma$  and  $H_\beta$  with parameters

$\Theta_\gamma$  and  $\Theta_\beta$  are defined to receive match and none-match vectors and produce some linear transformations by which the encoder embeddings are transformed. Finally, match transformations must be constructed perfectly; however, none-match ones are forced to have high reconstruction loss as follows:

$$\begin{aligned}
z_i &= F(X_i), \\
\gamma_{y_i^m} &= H_\gamma(l_{y_i^m}), & \gamma_{y_i^{nm}} &= H_\gamma(l_{y_i^{nm}}) \\
\beta_{y_i^m} &= H_\beta(l_{y_i^m}), & \beta_{y_i^{nm}} &= H_\beta(l_{y_i^{nm}}) \\
z_{i_{l_m}} &= \gamma_{y_i^m} \circ z_i + \beta_{y_i^m}, & z_{i_{l_{nm}}} &= \gamma_{y_i^{nm}} \circ z_i + \beta_{y_i^{nm}} \\
\hat{X}_i^m &= \mathcal{G}(z_{i_{l_m}}), & \hat{X}_i^{nm} &= \mathcal{G}(z_{i_{l_{nm}}}).
\end{aligned} \tag{44}$$

$$\mathcal{L}_r^m = \frac{1}{N} \sum_{i=1}^N \|X_i - \hat{X}_i^m\|_1$$

$$\mathcal{L}_r^{nm} = \frac{1}{N} \sum_{i=1}^N \|X_i^{nm} - \hat{X}_i^{nm}\|_1$$

where  $\hat{X}_i^{nm}$ s are sampled randomly based on randomly sampled none-match vectors, and the objective loss is:

$$\min_{\Theta_\gamma, \Theta_\beta, \Theta_\mathcal{G}} \alpha \cdot \mathcal{L}_r^m + (1 - \alpha) \cdot \mathcal{L}_r^{nm} \tag{45}$$

The embedding transformation technique is called FiLM Perez et al. (2018). This means that a given input would be reconstructed well only when the corresponding match vector is used. Therefore, for each test-time input, the reconstruction error under different match vectors is computed, and the rejection decision is made based on their minimum value. If the minimum value is greater than a threshold  $\tau$  it is discarded; else, the encoder’s output is assigned. To obtain  $\tau$  in a principled way, the optimum threshold is found using EVT on the distribution of match and none-match reconstruction error values i.e  $\|X_i - \hat{X}_i^m\|_1$  and  $\|X_i - \hat{X}_i^{nm}\|_1$  for each  $i$  and randomly sampled none-match vectors. Assuming the prior probability of observing unknown samples is  $p_u$ , the probability of error as a function of threshold  $\tau$  is shown in Eq. 46 where  $G_m$  and  $G_{nm}$  are the extreme value distributions of the match and none-match errors.

$$\begin{aligned}
\tau^* &= \min_{\tau} P_{\text{error}}(\tau) \\
&= \min_{\tau} [(1 - p_u) * P_m(r \geq \tau) + p_u * P_{nm}(-r \leq -\tau)] \\
&= \min_{\tau} [(1 - p_u) * (1 - G_m(\tau)) + p_u * (1 - G_{nm}(\tau))]
\end{aligned} \tag{46}$$

## 5.6 Deep Transfer Learning For Multiple Class Novelty Detection (DTL) Perera & Patel (2019):

This work also follows the idea of using a background dataset (called reference dataset). Similar to Dhamija et al. (2018), DTL addresses the deficiencies of using softmax loss in OSR. A new loss function called *membership loss* is proposed. Specifically, each activation score value  $f_i$  of the penultimate layer is normalized into  $[0, 1]$  using the sigmoid function. The normalized scores can be interpreted as the probability of the input image belonging to each individual class. Ideally, given the label  $y$ ,  $f(x)_i$  should be 1 when  $y = i$  and 0 otherwise. The loss function is defined as Eq. 47.

$$L_M(x, y) = [1 - \sigma(f(x)_y)]^2 + \lambda \cdot \frac{1}{c - 1} \sum_{i=1, i \neq y}^c [\sigma(f(x)_i)]^2 \tag{47}$$

Another technique for improving the detection performance is based on the “*globally negative filters*”. Filters that provide evidence for a particular class are considered as positive filters and vice versa. For pre-trained neural networks, it has been shown that only a small fraction of final feature maps are activated positively. Furthermore, some filters are always activated negatively, indicating irrelevance for all known classes. By discarding inputs that activate globally negative filters, a novel sample is less likely to produce high activation scores. To learn such filters for domain-specific task, DTL trains two parallel networks with shared weights up to the last layer—the first one solves a classification task on the reference dataset, and the second one solves the domain-specific classification tasks in combination with membership loss. If the reference and domain-specific datasets do not share much information, they provide negative filters for each other. Also, since the reference dataset consists of diverse classes, those learned filters can be considered globally negative filters. Finally, filters of the parallel network in combination with the confidence scores of the domain-specific classifier are used for novelty detection. Fig. 47 shows the overall network architecture.

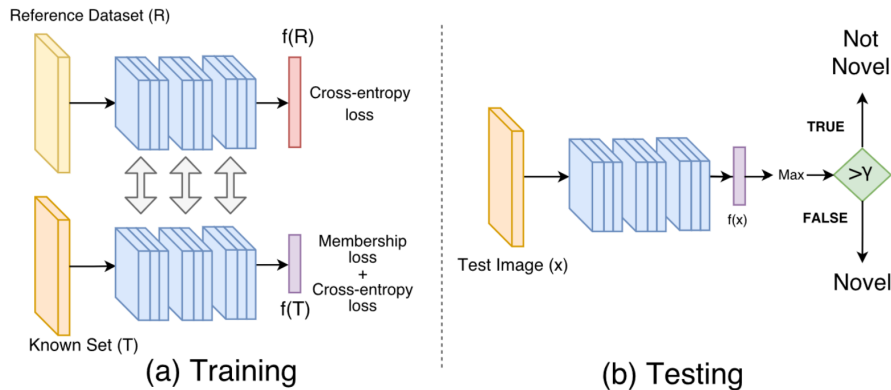

Figure 22: An overview of DTL method. Two parallel networks are trained to produce confidence scores and globally negative filters. The network above solves a simple classification task on the reference dataset, and the one below solves membership loss in combination with the domain-specific classification task. Test time detection is done by putting a threshold on the confidence of maximum class.

### 5.7 Classification-Reconstruction Learning for Open-Set Recognition (CROSR) Yoshihashi et al. (2019):

This work follows the similar idea as C2AE. In particular, CROSR employs an encoder network for classification and producing the latent vectors for reconstruction task. Importantly, the latent vector  $z$  used for the reconstruction task and penultimate layer  $y$  used for the classification task are not shared. The reason is that there is an excessive amount of information loss in the penultimate layer, which makes distinguishing between unknown and known samples hard. The overall procedure can be described as follows:

$$\begin{aligned}
 (y, z) &= f(x), \\
 p(C_i | x) &= \text{Softmax}_i(y), \\
 \hat{x} &= g(z)
 \end{aligned} \tag{48}$$

Moreover, to preserve information at different levels of abstraction, each layer of the encoder is compressed into a latent vector  $z_i$ . The latent vector is then decoded to minimize the reconstruction error of the corresponding layer as follows:

$$\begin{aligned}
 x_{l+1} &= f_l(x_l), \\
 z_l &= h_l(x_l), \\
 \hat{x}_l &= g_l(\hat{x}_{l+1} + \hat{h}_l(z_l))
 \end{aligned} \tag{49}$$

where  $f_l$  and  $g_l$  are layers of the encoder and decoder, respectively.  $\hat{h}_l$  is a reprojection to the original space of  $x_l$ . The autoencoding structure is based on a ladder network Rasmus et al. (2015).

The final latent vector  $\mathbf{z}$  is the concatenation of each  $z_i$ . EVT is employed as in OpenMax Bendale & Boulton (2016). However, the distance is not only computed on the penultimate layer  $y$  but also on the latent vector  $\mathbf{z}$ . Specifically, EVT is applied on the joint  $[y, \mathbf{z}]$ . Test-time detection is performed similar to OpenMax. Fig. 23 shows an overview of the method.

Figure 23: An overview of the proposed method compared to similar methods in the literature. As it is obvious, an encoder is used for the classification task, and the reconstruction task is done in a ladder network.

## 5.8 Generative-Discriminative Feature Representations For Open-Set Recognition (GDFR) Perera et al. (2020):

Similar to CROSR, this work trains a discriminative model in combination with a generative one. Discriminative approaches may lose important features that are utilitarian for distinguishing between seen and unseen samples. Generative modeling can provide complementary information. Similar to GT, GDFR employs SSL to improve the features of the discriminator. A shared network performs both the classification and SSL tasks, predicting the geometric transformations applied to the input.

Moreover, a generative model such as AE is used, producing reconstructed outputs  $\hat{x}$  for a given input  $x$ . Then the collection of input-reconstruction pairs  $(x, \hat{x})$  are passed to the discriminator network for classification and SSL tasks. The disparity between  $\hat{x}$  and  $x$  for unseen samples better helps the discriminator network detect them. Fig. 24 shows the method.

## 5.9 Conditional Gaussian Distribution Learning for Open Set Recognition (CGDL) Sun et al. (2020):

The main idea of this research is very similar to CROSR. However, CGDL uses the probabilistic ladder network based on variational encoding and decoding Sønderby et al. (2016). The overall encoding process for the  $l$ th layer is as follows:

$$\begin{aligned}
 x_l &= \text{Conv}(x_{l-1}) \\
 h_l &= \text{Flatten}(x_l) \\
 \mu_l &= \text{Linear}(h_l) \\
 \sigma_l^2 &= \text{Softplus}(\text{Linear}(h_l))
 \end{aligned} \tag{50}$$

where the "Softplus" operation is  $\log(1 + \exp(\cdot))$ ; and, the final representation vector  $z$  is defined as  $\mu + \sigma \circ \epsilon$  where  $\epsilon \sim N(0, I)$ . Similarly, for the decoding process we have:

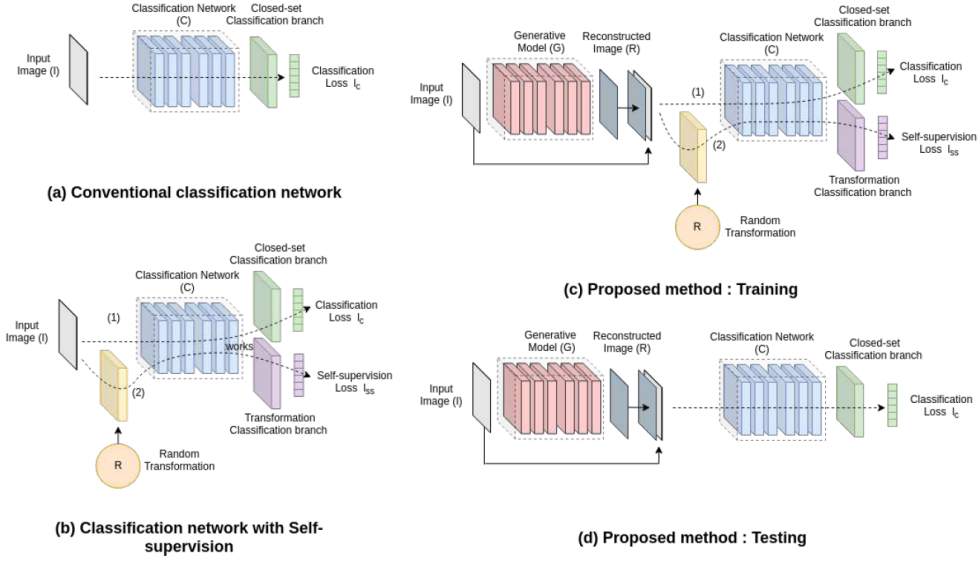

Figure 24: An overview of GDFR. As it can be seen, a classification network is trained on both SSL and classification tasks to make the learned features richer. Also, to benefit from generative modeling, each input is passed to an AE, and further tasks are applied on the joint of reconstructed and input images.

$$\begin{aligned}
 \hat{c}_{l+1} &= \text{Unflatten}(\hat{z}_{l+1}) \\
 \hat{x}_{l+1} &= \text{ConvT}(\hat{c}_{l+1}) \\
 \hat{h}_{l+1} &= \text{Flatten}(\hat{x}_{l+1}) \\
 \hat{\mu}_l &= \text{Linear}(\hat{h}_{l+1}) \\
 \hat{\sigma}_l^2 &= \text{Softplus}(\text{Linear}(\hat{h}_{l+1})) \\
 q\text{-}\mu_l &= \frac{\hat{\mu}_l + \hat{\sigma}_l^{-2} + \mu_l + \sigma_l^{-2}}{\hat{\sigma}_l^{-2} + \sigma_l^{-2}} \\
 q\text{-}\sigma_l^2 &= \frac{1}{\hat{\sigma}_l^{-2} + \sigma_l^{-2}} \\
 \hat{z}_l &= q\text{-}\mu_l + q\text{-}\sigma_l^2 \circ \epsilon
 \end{aligned} \tag{51}$$

During training, samples are passed into the encoder to estimate  $\mu$  and  $\sigma$  for each layer. The mean and variance can be used as priors for the corresponding decoding layer. The final embedding  $z$  of the encoder's top layer is used for the joint classification task and decoding process. The distribution of the encoder's final layer is forced to be similar to different multivariate Gaussian  $p_{\theta}^k(z) = N(z; \mu_k, I)$ , where  $k$  is the index of known classes and  $\mu_k$  is obtained by a fully-connected layer which maps the one-hot encoding of the input's label to the latent space. Each layer of the decoder is a Gaussian probability distribution in which a prior of its mean and variance is added by the corresponding layer of encoder statistics. Putting it together, the

training objective function is as follows:

$$\begin{aligned}
 \mathcal{L}_{KL} &= -\frac{1}{L} \left[ \text{KL}(q_\phi(z | x, k) || p_\theta^k(z)) \right. \\
 &\quad \left. + \sum_{l=1}^{K-1} \text{KL}(q_\theta(\hat{x}_l | \hat{x}_{l+1}, x) || q_\theta(\hat{x}_l | \hat{x}_{l+1})) \right] \\
 \mathcal{L}_r &= \|x - \hat{x}\|_1 \\
 \mathcal{L} &= -(\mathcal{L}_r + \lambda \cdot \mathcal{L}_c + \beta \cdot \mathcal{L}_{KL})
 \end{aligned}
 \tag{52}$$

where  $\mathcal{L}_c$  is the classification error and

$$\begin{aligned}
 q_\theta(\hat{x}_l | \hat{x}_{l+1}, x) &= N(\hat{x}_l; q\text{-}\mu_l, q\text{-}\sigma_l^2) \\
 q_\theta(\hat{x}_l | \hat{x}_{l+1}) &= N(\hat{x}_l; \hat{\mu}_l, \hat{\sigma}_l^2)
 \end{aligned}
 \tag{53}$$

At the test time, both the probability of final latent space with respect to  $p_\theta^k(z)$  and reconstruction error for each test input are used for detection. If an input is preserved, the output of classification is considered as the true class. As Fig. 25 shows, the latent vector  $z$  is considered as a prior of which the distribution of all classes should have a low KL distance. This is similar to the role of  $N(0, I)$  in the baseline VAE.

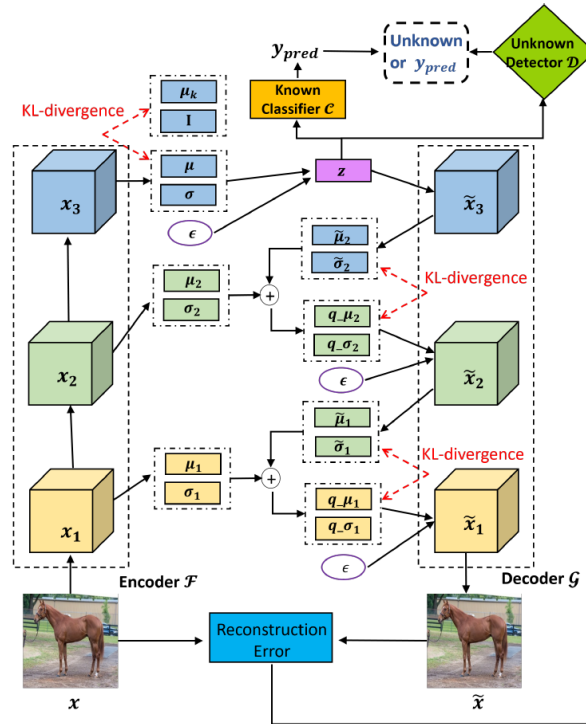

Figure 25: An overview of CGDL method. Compared to CROSR a probabilistic ladder network is used instead of a deterministic one; however, the classification task is similar. The probability distributions of the decoder network contain a prior from the corresponding layer statistics of the encoder network. Also, Despite VAE in which there is a prior  $N(0, I)$  on the latent space; here, the prior is learned, and each class distribution is tried to have a low KL distance with it.

### 5.10 Hybrid Models for Open Set Recognition Zhang et al. (2020):

In this work, a classification network is trained in combination with a flow-based generative model. Generative models in the pixel-level space may not produce discernible results for unseen and seen samples, and they

are not robust against semantically irrelevant noises. To address this issue, a flow-based model is applied to the feature representation space instead of pixel-level space (see Fig. 26). The reason for using flow-based models is their handy and comprehensive theoretical abilities. The training loss is a simple cross-entropy loss in combination with negative log-likelihood used for the training of the flow-based model. At the test time, the thresholding is applied to the likelihood of each input, and if it is preserved, the classifier’s output is assigned as the in-class label.

Figure 26: An overview of the hybrid models for open set recognition. As it can be seen, a classification network is trained in combination with a generative flow-based model. At the test time, the probability of the latent vector is considered as the criterion of rejection, and the classifier assigns a label if the input is not rejected.

### 5.11 Learning Open Set Network With Discriminative Reciprocal Points (RPL) Chen et al. (2020a):

Similar to Mem-AE, the idea of prototype features is used in this work. The goal is to learn a set of prototypes or reciprocal points, which can assign labels to each input based on the distance w.r.t each prototype. RPL helps the model better adjust the boundaries of different classes compared to softmax or OpenMax, and decreases the risk factor. Initially, random reciprocal points are chosen. The location of reciprocal points and the weights of a classifier network are adjusted to minimize the classification loss. This forces the network to locate features of each class near some specific reciprocal points to yield the desired class boundary using at least a set of points. To decrease the risk factor, samples of each class are forced to have a margin with respect to their reciprocal points, which is learned during the training process. Eq. 54 shows the mathematical formulation:

$$\begin{aligned}
 d(f_{\theta}(x), P^k) &= \frac{1}{M} \sum_{i=1}^M \|f_{\theta}(x) - p_i^k\|_2^2 \\
 p(y = k|x, f_{\theta}, P) &= \frac{e^{\gamma d(f_{\theta}(x), P^k)}}{\sum_{i=1}^N e^{\gamma d(f_{\theta}(x), P^i)}} \\
 L_o &= \frac{1}{M} \sum_{i=1}^M \|d(f_{\theta}(x), p_i^k) - R^k\|_2^2,
 \end{aligned} \tag{54}$$

where  $P^k$  is the set of  $k$ th class reciprocal points,  $p_i^k$  is a reciprocal point,  $M$  is the number of reciprocal points for each class,  $N$  is the number of classes,  $R^k$  is the margin for each class, and  $\gamma$  is a tunable hyper-parameter.

### 5.12 A Loss for Distance-Based Open Set Recognition (CAC) Miller et al. (2021):

The idea of this work is similar to RPL and GOAD. For each class, CAC defines an anchor vector of dimension  $N$ —the number of classes. For each vector, the element corresponding to the class label is 1 and 0 otherwise. For each training sample, the learning process forces its logit scores to be in a compact ball w.r.t true class anchor vector while having a large distance from anchors of other classes. CAC can also be seen as a multi-class DSVDD. The training loss function is as follows.

$$\begin{aligned}
\mathbf{d} &= e(\mathbf{z}, \mathbf{C}) = (\|\mathbf{z} - \mathbf{c}_1\|_2, \dots, \|\mathbf{z} - \mathbf{c}_N\|_2) \\
\mathcal{L}_T(\mathbf{x}, y) &= \log\left(1 + \sum_{j \neq y}^N e^{d_y - d_j}\right) \\
\mathcal{L}_A(\mathbf{x}, y) &= d_y = \|f(x) - \mathbf{c}_y\|_2 \\
\mathcal{L}_{CAC}(\mathbf{x}, y) &= \mathcal{L}_T(\mathbf{x}, y) + \lambda \cdot \mathcal{L}_A(\mathbf{x}, y)
\end{aligned} \tag{55}$$

### 5.13 Few-Shot Open-Set Recognition Using Meta-Learning (PEELER) Liu et al. (2020a):

In this work, the idea of meta-learning is combined with open set recognition. Meta-learning enable learning general features that can be easily adapted to any unseen task. Meta-learning is also called learning to learn. Due to the ability to work in few-shot settings, meta-learning can be useful in low data regimes. At the meta iteration  $i$ , meta-model  $h$  is initialized with the one produced by the previous meta-iteration. Let  $(S_i^s, T_i^s)_{i=1}^{N^s}$  be a meta-training dataset with  $N^s$  number of training problems, two steps are performed. First, an estimate  $h'$  of the optimal model for the training set  $S_i^s$  is produced. Then the test set  $T_i^s$  is used for finding a model with a suitable loss function  $L$  as the Eq. 56 shows.

$$h^* = \arg \min_h \sum_{(x_k, y_k) \in T_i^s} L[y_k, h'(x_k)] \tag{56}$$

To adopt meta-learning in OSR, a classification loss in combination with open-set loss is used. Moreover, the test set  $T_i^s$  is augmented with some unseen samples. The overall loss function is defined as Eq. 57, where  $L_c$  is a simple classification loss, and  $L_o$  maximizes the entropy of unknown samples on the known classes.

$$\begin{aligned}
h^* = \arg \min_h \left\{ \sum_{(x_k, y_k) \in C_i^s \in T_i^s | y_k} L_c[y_k, h'(x_k)] \right. \\
\left. + \lambda \cdot \sum_{(x_k, y_k) \in T_i^s | y_k \in C_i^u} L_o[h'(x_k)] \right\}
\end{aligned} \tag{57}$$

At the test time, the average features of correctly classified samples is obtained as a prototype point and used for the rejection of unseen samples.

### 5.14 Learning Placeholders for Open-Set Recognition (PROSER) Zhou et al. (2021):

This work tries to train a classifier that can place between target class and non-target classes. A dummy classifier is added to the softmax layer of the model with a shared feature extractor. Then it is forced to have the second maximum value for the correctly classified samples. When the classifier encounters novel inputs, the dummy classifier produces high values since all known classes are non-targets. Dummy classifier can be seen as the instance-dependent threshold which can well fit every known class. The loss function is defined as the Eq. 58, where  $\hat{f}((x)/y)$  means making the most probable class zero.

$$L_1 = \sum_{(x, y) \in D_{tr}} l(\hat{f}(x), y) + \beta l(\hat{f}((x)/y, k + 1)) \tag{58}$$

Moreover, the mixup technique Verma et al. (2019) is added to the loss function to boost unseen samples detection. The mixup representations are introduced to approximate the unseen sample's distribution and should be classified as the dummy class  $k + 1$ . Finally, rejecting each test time sample is done based on the probability of the dummy class.

### 5.15 Counterfactual Zero-Shot and Open-Set Visual Recognition Yue et al. (2021):

This work attempts to make abnormal samples in a counter-factual faithful way. As the paper mentions, most of the generative approaches such as G-OpenMax do not produce desired fake samples, the distributions of which do not resemble real distribution of unseen samples. To this end, a  $\beta$ -VAE Higgins et al. (2016) is used to make sample attribute variable  $Z$  and the class attribute variable  $Y$  independent. The  $\beta$ -VAE loss function is similar to simple VAE; however, the  $KL$  term is induced by a coefficient  $\beta$ . This is shown to be highly effective in learning a disentangled sample attribute  $Z$  Higgins et al. (2016). For disentangling  $Y$  from  $Z$ , the proposed approach makes counter-factual samples by changing the variable  $Y$  to have a large distance with the given input  $x$  in spite of samples that are generated by changing the variable  $Z$ . To make counter-factual samples faithful, a Wasserstein GAN Arjovsky et al. (2017) loss is used for a discriminator  $D(X, Y)$ , which verifies the correspondence between the generated counter-factual image and the assigned label. At last, generated samples can be used to boost the performance of any OSR problem.

### 5.16 OpenGAN: Open-Set Recognition via Open Data Generation Kong & Ramanan (2021): (R1)

This work argues that using an easily accessible auxiliary outlier dataset can improve the open-set recognition performance as mentioned in Ruff et al. (2019) and Hendrycks et al. (2018). However, the auxiliary dataset might poorly generalize to diverse open-set data that are even likely to be faced. Therefore, close to Zaheer et al. (2020) a GAN-based approach is employed to generate fake samples that are supposed to mimic the distribution of the open-set data. Although, as mentioned in Zaheer et al. (2020), GAN-based methods suffer from instability when used in the one-class training setup, in the OSR setup, labeled closed-set data is available which can be used to find the best stopping point during training. Furthermore, fake samples can be generated according to the feature space of closed-set samples passed through a pre-trained  $K$ -way classification model, which significantly reduces the dimensionality of the problem and helps stability. This work shows that a well-selected GAN-discriminator using a validation set achieves SOTA on OSR. Fig. 27 shows that at first, a closed-set classifier is trained on the given training dataset and is kept fixed afterward. Then, a GAN-based framework is trained on the embeddings of the closed-set and outlier images, which forces the generator to produce semantically fake outputs that are hard to be detected as fake for the discriminator. Eq. 59 shows the mathematical formulation of the loss function, where  $\lambda_G$  controls the contribution of generated fake samples generated by  $G$ , and  $\lambda_o$  adjusts the effect of auxiliary outlier dataset.

$$\max_D \min_G \mathbb{E}_{x \sim P_{\text{closed}}} [\log(D(x))] + \lambda_o \cdot \mathbb{E}_{\hat{x} \sim P_{\text{open}}} [\log(1 - D(\hat{x}))] + \lambda_G \cdot \mathbb{E}_{z \sim N} [\log(1 - D(G(z)))] \quad (59)$$

Figure 27: An overview of the OpenGAN method. Unlike pure GAN-based methods or Outlier Exposure, fake samples are generated in the latent space while a discriminator is trained to distinguish between the closed-set samples’ embedding and outlier inputs. Closed-set embeddings are produced using a trained  $K$ -way closed-set classification model that is kept frozen afterward. In this way, the fake generator  $G$  is pushed towards making features, matching outlier images’ embeddings.

### 5.17 Open-set Recognition: A Good Closed-set Classifier Is All You Need? Vaze et al. (2021): (R1)

This work provides a comprehensive investigation through the correlation of closed-set accuracy and open-set performance of different deep architectures. It is shown that not only the closed-set accuracy of a model is

highly correlated with its OSR performance, but also this correlation holds across a variety of loss objectives and architectures. This is surprising because stronger closed-set classifiers are more likely to overfit to the training classes and perform poorly in OSR. Fig. 28 illustrates the mentioned relationship for different architectures and within the ResNet family architectures. Another contribution of this work is providing a Semantic Shift Benchmark (SSB), which unlike common approaches of utilizing a single test set for the evaluation, makes two 'Easy' and 'Hard' sets based on the semantic similarity of the open-set categories to the training classes. The ability of a model to detect semantic novelty as opposed to the low-level distributional shift is better captured in this manner.

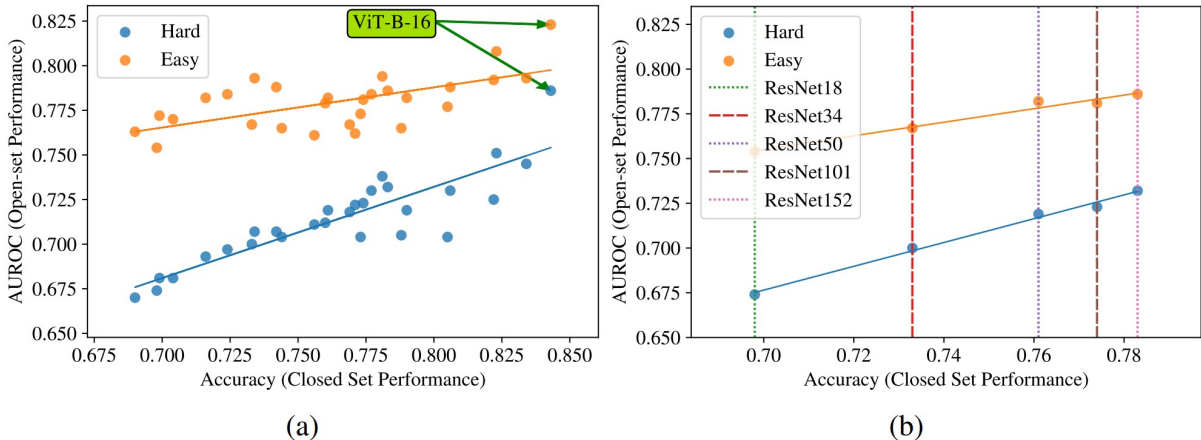

Figure 28: (a) The performance of different deep model architectures on the ImageNet dataset. The ImageNet-21K-P dataset is used to generate 'Easy' and 'Hard' OSR splits. (b) The performance of different ResNet families on the ImageNet.

## 6 Out-of-distribution Detection

OOD detection aims to identify test-times samples that are semantically different from the training data categories, and therefore should not be predicted into the known classes. For instance, one could train the model on CIFAR-10 (as in-distribution data), and then evaluating on CIFAR-100 Netzer et al. (2011) as an out-of-distribution dataset, as CIFAR-10 and CIFAR-100 have mutually exclusive classes. In the multi-class setting, the problem of OOD detection is canonical to OSR: accurately classifying samples from the known classes while detecting the unknowns. However, OOD detection encompasses a broader spectrum of learning tasks (e.g., multi-label classification) and solution space (e.g., density estimation without classification). Some approaches relax the constraints imposed by OSR and achieve strong performance. We next review some of recent OOD detection works and their differences.

### 6.1 A Baseline for Detecting Misclassified and Out-of-Distribution Examples in Neural Networks Hendrycks & Gimpel (2016):

This work coined “out-of-distribution detection” and showed how to evaluate deep learning out-of-distribution detectors. Whereas previous anomaly detection works for deep classifiers often had low-quality or proprietary datasets, this repurposed existing datasets to create out-of-distribution datasets, enabling easier evaluation. It proposes using the maximum softmax probability (MSP) to detect out-of-distribution samples, namely  $\max_k p(y = k | x)$ . A test sample with a large MSP score is detected as an in-distribution (ID) example rather than out-of-distribution (OOD) example. It showed that a simple maximum probability score can be useful for detection in vision, natural language processing, and speech recognition settings, but there is much room for improvement. It also showed  $p(y | x)$  models can be useful for out-of-distribution detection and that  $p(x)$  models are not necessarily needed. Until now, it still serves as a general-purpose baseline that is nontrivial to surpass. Concurrent OSR work proposed additional modifications to softmax probabilities for detection Bendale & Boulton (2016).

## 6.2 Enhancing The Reliability of Out-of-distribution Image Detection in Neural Networks (ODIN) Liang et al. (2017):

In this work, a technique called temperature scaling was employed. Although it has been used in other domains such as knowledge distillation Hinton et al. (2015), the main novelty of this work is showing the usefulness of this technique in the OOD domain. In temperature scaling, the softmax score is computed as in Eq. 60. OOD samples are then detected at the test time based on thresholding the maximum class probability. This simple approach, in combination with adding a small controlled noise, has shown significant improvement compared to the baseline approach MSP. ODIN further shows that adding one step gradient to the inputs in the direction of improving the maximum score has more effect on the in-class samples, and pushes them to have larger margin with the OOD samples.

$$S_i(x; T) = \frac{\exp(f_i(x)/T)}{\sum_{j=1}^N \exp(f_j(x)/T)} \quad (60)$$

The paper also provided mathematical explanation for the effect of temperature scaling on out-of-distribution detection. This can be seen in the Taylor approximation of the softmax score (expanded around the largest logit output  $f_{\hat{y}}(x)$ ):

$$\begin{aligned} S_i(x; T) &= \frac{\exp(f_i(x)/T)}{\sum_{j=1}^N \exp(f_j(x)/T)} \\ &= \frac{1}{\sum_{j=1}^N \exp(\frac{f_j(x)-f_i(x)}{T})} \\ &\approx \frac{1}{N - \frac{1}{T} \sum_{j=1}^N [f_{\hat{y}}(x) - f_j(x)] + \frac{1}{2T^2} \sum_{j=1}^N [f_{\hat{y}}(x) - f_j(x)]^2} \end{aligned} \quad (61)$$

A sufficiently large temperature  $T$  has a strong smoothing effect that transforms the softmax score back to the logit space—which effectively distinguishes ID vs. OOD. In particular, the ID/OOD separability is determined by the  $U_1 = \sum_{j=1, j \neq \hat{y}}^N [f_{\hat{y}}(x) - f_j(x)]$  and  $U_2 = \sum_{j=1, j \neq \hat{y}}^N [f_{\hat{y}}(x) - f_j(x)]^2$ . The former measures the extent to which the largest unnormalized output of the neural network deviates from the remaining outputs; while the latter measures the extent to which the remaining smaller outputs deviate from each other. For the in-class samples,  $U_1$  and  $E[U_2 | U_1]$  are higher than OOD ones. Mathematically and empirically, ODIN is not sensitive to  $T$  when it is large enough to satisfy the Taylor approximation. For example, the paper shows that simply applying  $T = 1000$  can yield effective performance boost without hyper-parameter tuning. In general, using temperature scaling can improve the separability more significantly than input preprocessing.

Note that ODIN differs from confidence calibration, where a much milder  $T$  is employed. While calibration focuses on representing the true correctness likelihood of ID data only, the ODIN score is designed to maximize the gap between ID and OOD data and may no longer be meaningful from a predictive confidence standpoint. As seen in Fig. 29, the ODIN scores are closer to  $1/N$  where  $N$  is the number of classes.

Figure 29: An overview of ODIN, a post-hoc method that uses temperature scaling and input perturbation to amplify the ID/OOD separability.

### 6.3 A Simple Unified Framework for Detecting Out-of-Distribution Samples and Adversarial Attacks Lee et al. (2018):

This work was inspired from the idea of Linear Discriminant Analysis (LDA) in which  $P(X = x | Y = y)$  is considered to be a multivariate Gaussian distribution. In order for  $P(Y = y | X = x)$  to be similar to a softmax form, it is assumed that the feature space of the penultimate layer follows the Gaussian distribution. Therefore, a mean and variance vector is simply estimated from features of each class, and a multivariate Gaussian is fit to them. In order to check validity of the assumptions, it uses the Mahalanobis distance of the test time images to perform the classification instead of the softmax function. Surprisingly, the results are comparable or better than softmax, which supports the assumptions. It performs OOD detection using Mahalanobis distance to the closest class-conditional Gaussian distribution. Furthermore, to improve the performance, features in different layers are ensembled and a small controlled noise is added to test samples as shown in Eq. 62, where  $M(x)$  is the Mahalanobis distance with mean of the closest class-conditional Gaussian distribution. A similar idea has been discussed earlier in Rippel et al. (2021).

$$\hat{x} = x + \epsilon \cdot \text{sign}(\nabla_x M(x)) \quad (62)$$

### 6.4 Predictive Uncertainty Estimation via Prior Networks (DPN) Malinin & Gales (2018):

This work discusses three different sources of uncertainty: (1) data uncertainty, (2) distributional uncertainty, and (3) model uncertainty. The importance of breaking down the final uncertainty into these terms was discussed. For instance, model uncertainty might happen because of the model’s lack of capacity to approximate the given distribution well. On the other hand, data uncertainty might happen because of the intrinsic intersection of similar classes. For instance, classifying between different kinds of dogs has more data uncertainty than solving a classification problem with completely separate classes. Distributional uncertainty is related to the problem of AD, ND, OSR, and OOD detection. The goal of this work was to estimate the distributional uncertainty for each input and compare it with the data and model uncertainties. Data uncertainty  $P(w_c | x^*, \theta)$  can be defined by the posterior distribution over class labels given a set of parameter  $\theta$ . Model uncertainty  $P(\theta | D)$  is defined by the posterior distribution over the parameter given data  $D$ . These two types of uncertainties could be combined to give rise to the distributional uncertainty, as shown in Eq. 63.

$$P(w_c | x^*, D) = \int P(w_c | x^*, \theta) P(\theta | D) d\theta \quad (63)$$

As computing the integral is not tractable, the above formula is usually converted into the Eq. 64, where  $q(\theta)$  is an approximation of  $P(\theta | D)$ .

$$P(w_c | x^*, D) \approx \frac{1}{M} \sum_{i=1}^M P(w_c | x^*, \theta^i), \theta^i \sim q(\theta) \quad (64)$$

Each  $P(w_c | x^*, D)$  can then be seen as a categorical distribution located on a simplex, as shown in Fig. 30.

Figure 30: The figure shows a distribution over the categorical distributions for modeling uncertainty using both model uncertainty and data uncertainty.

Now to extract distributional uncertainty from the model uncertainty, Eq. 64 is decomposed into the following Eq. 65.

$$P(w_c | x^*, D) = \iint P(w_c | \mu)P(\mu | x^*, \theta)P(\theta | D) d\mu d\theta, \quad (65)$$

where  $P(w_c | \mu)$  is a categorical distribution given a realization from a Dirichlet distribution,  $P(\mu | x^*, \theta)$  is the Dirichlet distribution given the input and model parameters  $\theta$ , and  $P(\theta | D)$  is the distribution over model parameters given the dataset  $D$ . For simplicity, in this work  $P(\theta | D)$  is equal to  $\delta(\theta - \hat{\theta})$  and is produced by the output of a deep network. Therefore  $P(\mu | x^*, \theta) = P(\mu | x^*, \hat{\theta}) = \text{Dir}(\mu | \alpha)$ , and  $\alpha = f(x^*, \hat{\theta})$ , where  $f(\cdot, \cdot)$  is represented by a deep neural network.

At the training time, the Dirichlet Prior Network (DPN) is expected to yield a flat distribution over the simplex for OOD samples, indicating large uncertainty in the mapping from  $x$  to  $y$ . Some out-of-distribution data is used to minimize the KL distance of  $\text{Dir}(\mu | \alpha)$  and the flat Dirichlet distribution. For the in-class samples, the KL divergence between  $\text{Dir}(\mu | \alpha)$  and a sharp, sparse Dirichlet distribution is minimized. The objective Dirichlet distributions are obtained by pre-setting their parameters during training process. During test time, different criterion such as max probability, last layer’s entropy, and distributional uncertainty as in Eq. 66 are used for OOD detection.

$$I(y, \mu | x^*, D) = H[E_{P(\mu|x^*, D)}[P(y | \mu)]] - E_{P(\mu|x^*, D)}[H[P(y | \mu)]] \quad (66)$$

### 6.5 Confidence-calibrated Classifiers for Detecting Out-of-distribution Samples Lee et al. (2017):

This work attempted to maximize the entropy of confidence scores for OOD samples, similar to Dhamija et al. (2018). Similar to Neal et al. (2018), it generates OOD samples by jointly training a GAN and a classifier. As shown in Eq. 67, the first term solves a classification task on in-class samples, the second term uses KL divergence to make the confidence score distribution of generated OOD samples uniform. The remainder terms train the GAN on the in-class samples. Note that, the GAN is forced to generate high-quality OOD samples that produce high uncertainty when they are passed to the classifier. Therefore, the generated samples are located on the boundaries of in-class and outlier distributions. The paper also shows that leveraging on-boundary in-class samples significantly improves its confidence calibration.

$$\begin{aligned} & \min_G \max_D \min_{\theta} E_{P_{\text{in}}(\hat{x}, \hat{y})}[-\log P_{\theta}(y = \hat{y} | \hat{x})] \\ & + \beta E_{P_G(x)}[\text{KL}(U(y) || P_{\theta}(y | x))] + E_{P_{\text{in}}(\hat{x})}[\log D(x)] \\ & + E_{P_G(x)}[\log(1 - D(x))] \end{aligned} \quad (67)$$

Test time OOD detection is done based on thresholding of the maximum softmax value.

### 6.6 Deep Anomaly Detection with Outlier Exposure (OE) Hendrycks et al. (2018):

This work introduced Outlier Exposure (OE) and reported extensive experiments on its usefulness for various settings. When applied to classifiers, the Outlier Exposure loss encourages models to output a uniform softmax distribution on outliers, following Lee et al. (2017). More generally, the Outlier Exposure objective is

$$\mathbb{E}_{(x,y) \sim \mathcal{D}_{\text{in}}} [\mathcal{L}(f(x), y) + \lambda \cdot \mathbb{E}_{x' \sim \mathcal{D}_{\text{out}}^{\text{OE}}} [\mathcal{L}_{\text{OE}}(f(x'), f(x), y)],$$

assuming a model  $f$ , the original learning objective  $\mathcal{L}$ ; when labeled data is not available,  $y$  can be ignored. Models trained with this objective can have their maximum softmax probabilities Hendrycks & Gimpel (2016) better separate in- and out-of-distribution examples. To create  $\mathcal{D}_{\text{out}}^{\text{OE}}$ , data unlike the training data will need to be scraped or curated or downloaded. Samples from  $\mathcal{D}_{\text{out}}^{\text{OE}}$  are gathered from already existing and available datasets that might not be directly related to the task-specific objective function; however, they can significantly improve the performance because they contain many diverse variations. Concurrent work Dhamija et al. (2018) explores a similar intuition for small-scale image classification, while Outlier Exposure shows how to improve OOD detection for density estimation models, natural language processing models, and small- and large-scale image classifiers.

### 6.7 Using Self-Supervised Learning Can Improve Model Robustness and Uncertainty Hendrycks et al. (2019a):

This work investigated the benefits of training supervised learning tasks in combination with SSL methods in improving robustness of classifiers against simple distributional shifts and OOD detection tasks. To do so, an auxiliary rotation prediction was added to a simple supervised classification. The work measures robustness against simple corruptions such as Gaussian noise, shot noise, blurring, zooming, fogging etc. It has been observed that although auxiliary SSL tasks do not improve the classification accuracy, the model’s robustness and detection abilities are significantly improved. Additionally, when the total loss function is trained in an adversarially robust way, the robust accuracy is improved. Finally, the method is tested in the ND setting using rotation prediction, and horizontal and vertical translation prediction similar but simpler than GT or GOAD. They also test in the setting of multiclass classification setting and find that auxiliary self-supervised learning objectives improves the maximum softmax probability detector Hendrycks & Gimpel (2016). In addition, similar to Dhamija et al. (2018) and Lee et al. (2017), they attempted to make distribution of the confidence layer for some background or outlier samples uniform. Outliers are selected from other accessible datasets, as in Outlier Exposure Hendrycks et al. (2018).

### 6.8 Unsupervised Out-of-Distribution Detection by Maximum Classifier Discrepancy Yu & Aizawa (2019):

This work relies on a surprising fact—two classifiers trained with different random initializations can act differently on unseen test time samples at their confidence layers. Motivated by this, the work attempts to increase the discrepancy on unseen samples and reduce the discrepancy on seen ones. The discrepancy loss is the difference between the first classifier’s last layer entropy and that of the second one. This forces the classifiers to have the same confidence scores for in-class inputs, yet increases their discrepancy for the others. Fig. 31 shows the overall architecture. First, two classifiers are trained on the in-class samples and are encouraged to produce the same confidence scores. Second, an unlabeled dataset containing both OOD and in-class data is employed to maximize their discrepancy on outliers while preserving their consistency on inliers.

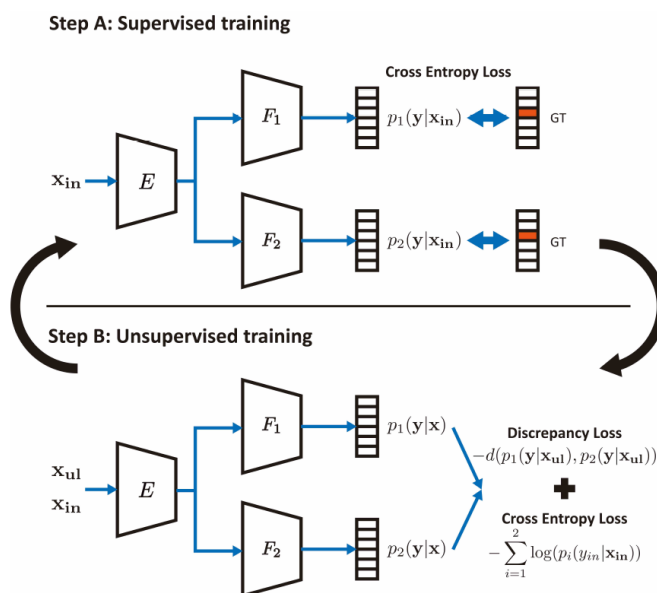

Figure 31: The overall architecture of Yu & Aizawa (2019). As it can be seen, at the first step, both of the classifiers are trained. Then, at the next step, an auxiliary discrepancy loss is added to the supervised classification to adjust the boundaries of in-class and OOD samples.

## 6.9 Why ReLU Networks Yield High-Confidence Predictions Far Away From the Training Data Hein et al. (2019):

This work proved that ReLU networks produce piece-wise affine functions; therefore, they can be written as  $f(x) = V^l x + a^l$  on the polytope  $Q(x)$  as follows:

$$\begin{aligned}\Gamma_{l,i} &= \{z \in R^d \mid \Delta^l(x)(V_i^l z + a_i^l \geq 0)\} \\ Q(x) &= \cap_{l=1,\dots,L} \cap_{i=1,\dots,n_l} \Gamma_{l,i},\end{aligned}\tag{68}$$

$n_l$  and  $L$  are the number of hidden units in the  $l$ th layer and the total number of layers, respectively. The following theorem proves the deficiency of ReLU networks.

*Theorem. 1* Let  $R^d = \cup_{l=1}^R Q_l$  and  $f(x) = V^l x + a^l$  be the piecewise affine representation of the output of a ReLU network on  $Q_l$ . Suppose that  $V^l$  does not contain identical rows for all  $l = 1, \dots, R$ . Then for almost any  $x \in R^d$  and  $\epsilon \geq 0$  there exists an  $\alpha$  and a class  $k \in \{1, \dots, K\}$  such that for  $z = \alpha x$  it holds

$$\frac{e^{f_k(z)}}{\sum_{r=1}^K e^{f_r(z)}} \geq 1 - \epsilon\tag{69}$$

The equation goes to 1 if  $\alpha \rightarrow \infty$ . From this, we can imply that for ReLU networks there exist infinitely many inputs which yield high confidence predictions. Note that arbitrarily high confidence prediction can not be obtained due to the bounded domain of inputs. In order to relieve this problem, a technique that is called confidence enhancing data augmentation is used, as the Eq. 70 shows.

$$\begin{aligned}\frac{1}{N} \sum_{i=1}^N L_{\text{CE}}(y_i, f(x_i)) + \lambda \cdot E[L_{p_{\text{out}}}(f, Z)] \\ L_{p_{\text{out}}} = \max_{l=1,\dots,K} \log \left( \frac{e^{f_l(z)}}{\sum_{k=1}^K e^{f_k(z)}} \right)\end{aligned}\tag{70}$$

where  $p_{\text{out}}$  and  $p_{\text{in}}$  are in-class and out-of-distribution distributions respectively, which we are certain that the set of the intersection of their supports has zero or close to zero probability mass. An example of such an out-distribution pout would be the uniform distribution on  $[0, 1]^{w \times h}$  or other noise distributions.

The above training objective needs many samples to enforce low confidence on the entire out-distribution, an alternative technique called adversarial confidence enhancing training (ACET) is used. ACET uses the idea of adversarial robust training to not only minimize the objective function at each point but also the worst case in a neighborhood of the point as Eq. 71 shows.

$$\frac{1}{N} \sum_{i=1}^N L_{\text{CE}}(y_i, f(x_i)) + \lambda \cdot E[\max_{\|u-Z\|_p \leq \epsilon} L_{p_{\text{out}}}(f, u)]\tag{71}$$

At the test time, a thresholded confidence score is used to distinguish between inliers and outliers.

## 6.10 Do Deep Generative Models Know What They Don't Know? Nalisnick et al. (2018):

This work shows that generative models surprisingly assign higher likelihood scores to outliers. This holds for VAEs, auto-regressive models, and different kinds of flow-based methods. In the generative modeling, usually, a parametric model on the data distribution is assumed as  $p_\theta(x)$ . Then, it finds the best  $\theta$  that minimizes the KL distance between the true but unknown distribution  $p^*$  and  $p$ , which is equal to maximizing the likelihood of  $p_\theta(x)$  on the input distribution, as the Eq. 72 shows.

$$\text{KL}[p^*||p_\theta(x)] = \int p^*(x) \log \frac{p^*(x)}{p_\theta(x)} dx \approx -\frac{1}{N} \log p_\theta(X) - H[p^*] \quad (72)$$

Also, assuming the existence of a latent space  $Z$  the integrals can be written as Eq. 73 where  $Z$  and  $X$  are hidden and input variables, respectively. Let  $f$  be a diffeomorphism from the data space to a latent space, which commonly happens in flow-based modelings, where  $|\frac{\partial f}{\partial x}|$  is known as the volume element.

$$\int_z p_z(z) dz = \int_x p_z(f(x)) \left| \frac{\partial f}{\partial x} \right| dx = \int_x p_x(x) dx \quad (73)$$

The parameters of  $p$  can be decomposed as  $\theta = \{\phi, \psi\}$  with  $\phi$  being the diffeomorphism's parameters, i.e.  $f(x; \phi)$ , and  $\psi$  being the auxiliary distribution's parameters, i.e.  $p(z; \psi)$ . Then the objective function can be written as the Eq. 74.

$$\begin{aligned} \theta^* &= \arg \max_\theta \log p_\theta(X) = \\ &\arg \max_{\phi, \psi} \sum_{i=1}^N \log p_z(f(x_n, \phi), \psi) + \log \left| \frac{\partial f_\phi}{\partial x_n} \right| \end{aligned} \quad (74)$$

An interesting aspect of the objective function above is that it encourages the function  $f$  to have high sensitivity to small changes of input samples  $x_n$ . It is mentioned in the paper that if we plot the effect of each term separately, the first term shows the desired behavior for inliers and outliers, but the second term causes the problem. While changing  $f$  to constant-volume (CV) transformations Dinh et al. (2014) can alleviate the problem, but not entirely. Finally, using the second-order expansion of the log-likelihood around an interior point  $x_0$ , it has been shown that the assigned likelihoods have a direct relation to the model curvature and data's second moment. Therefore, the problem of generative models might be fundamental. Eq. 75 shows the details of expansion where  $Tr$  means trace operation.

$$\begin{aligned} 0 &\leq E_q[\log p(x, \theta)] - E_{p^*}[\log p(x, \theta)] \approx \\ &\nabla_{x_0} \log p(x_0, \theta)^T (E_q[x] - E_{p^*}[x]) \\ &+ \frac{1}{2} \text{Tr}\{\nabla_{x_0}^2 \log p(x_0, \theta)(\Sigma_q - \Sigma_{p^*})\} \end{aligned} \quad (75)$$

### 6.11 Likelihood Ratios for Out-of-Distribution Detection Ren et al. (2019):

This paper employs likelihood ratio to alleviate the problem of OOD detection in generative models. The key idea is to model the background and fore-ground information separately. Intuitively, background information is assumed to be harmed less than fore-ground information when semantically irrelevant information are added to the input distribution. Therefore, two autoregressive models are trained on noisy and original input distribution, and their likelihood ratio is defined as Eq. 76.

$$\begin{aligned} \text{LLR}(x) &= \log \frac{p_\theta(X)}{p_{\theta_0}(X)} = \log \frac{p_\theta(X_B)p_\theta(X_F)}{p_{\theta_0}(X_B)p_{\theta_0}(X_F)} \\ &\log \frac{p_\theta(X_F)}{p_{\theta_0}(X_F)} = \log p_\theta(X_F) - \log p_{\theta_0}(X_F) \end{aligned} \quad (76)$$

At the test time, a thresholding method is used on the likelihood ratio score.

### 6.12 Generalized ODIN Hsu et al. (2020):

As an extension to ODIN Liang et al. (2017), this work proposes a specialized network to learn temperature scaling and a strategy to choose perturbation magnitude. G-ODIN defines an explicit binary domain variable  $d \in \{d_{\text{in}}, d_{\text{out}}\}$ , representing whether the input  $x$  is inlier (i.e.  $x \sim p_{\text{in}}$ ). The posterior distribution can be decomposed into  $p(y | d_{\text{in}}, x) = \frac{p(y, d_{\text{in}} | x)}{p(d_{\text{in}} | x)}$ . Note that in this formulation, the reason of assigning overconfident scores to outliers seems more obvious, since the small values of  $p(y, d_{\text{in}} | x)$  and  $p(d_{\text{in}} | x)$  produce the high value of  $p(y | d_{\text{in}}, x)$ . Therefore, they are decomposed and estimated using different heads of a shared feature extractor network as  $h_i(x)$  and  $g(x)$  for  $p(y | d_{\text{in}}, x)$  and  $p(d_{\text{in}} | x)$  respectively. This structure is called dividend/divisor and the logit  $f_i(x)$  for class  $i$  can be written as  $\frac{h_i(x)}{g(x)}$ . The objective loss function is a simple cross entropy, similar to previous approaches. Note that the loss can be minimized by increasing  $h_i(x)$  or decreasing  $g(x)$ . For instance, when the data is not in the high-density areas of in-distribution,  $h_i(x)$  might be small; therefore,  $g(x)$  is forced to be small to minimize the objective function. In the other case,  $g(x)$  are encouraged to have larger values. Therefore, they approximate the role of aforementioned distributions  $p(y | d_{\text{in}}, x)$  and  $p(d_{\text{in}} | x)$ . At the test time  $\max_i h_i(x)$  or  $g(x)$  are used. Fig. 32 shows an overview of the method.

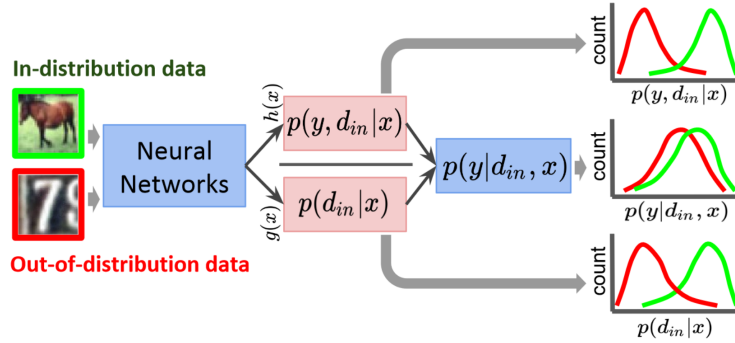

Figure 32: The overall architecture of Generalized ODIN. As it is obvious, different heads are applied on the penultimate layer to model the mentioned distributions.

### 6.13 Background Data Resampling for Outlier-Aware Classification Li & Vasconcelos (2020):

As mentioned before, in AD, ND, OSR, and OOD detection, some methods use a background or outlier dataset to boost their performances. However, to avoid different kinds of biases, the size of auxiliary datasets becomes important. In this work, a re-sampling technique is proposed to select an optimal number of training samples from the outlier dataset such that on-boundary samples play a more influential role in the optimization task. The work first provided an interesting probabilistic interpretation on outlier exposure technique. The loss function can be written as Eq. 79, where  $L_{\text{cls}}$  and  $L_{\text{uni}}$  are shown in Eq. 77 and Eq. 78 respectively.

$$L_{\text{cls}}(f(x; \theta), y) = -\log f_y(x; \theta) \quad (77)$$

$$L_{\text{uni}}(f(x; \theta)) = -\frac{1}{K} \sum_{k=1}^K \log f_k(x; \theta) - \log K \quad (78)$$

$$L(\theta; p, q) = E_{X, Y \sim p(\cdot, \cdot)}[L_{\text{cls}}(f(X; \theta); Y)] + \alpha E_{X \sim q(\cdot)}[L_{\text{uni}}(f(X; \theta))]. \quad (79)$$

By expanding Eq. 79 and taking its gradient w.r.t. classifier logits, the optimal classifier is obtained as Eq. 80 shows.

$$\begin{aligned} f_k^*(x) &= c(x)p_{Y|X}(k|x) + \frac{1-c(x)}{K} \\ c(x) &= \frac{p_X(x)}{p_X(x) + \alpha q_X(x)}, \end{aligned} \quad (80)$$

where  $c(x)$  can be seen as the relative probability of a sample  $x$  being in-class distribution  $p$  or background distribution  $q$  with the ratio  $\alpha$ . Suppose  $D'_b$  is the re-sampled dataset and  $D_b$  is the given background one, OOD detection loss after reweighting can be written as:

$$\begin{aligned} L_{\text{out}}(\theta; w) &= \frac{1}{|D'_b|} \sum_{(x,y) \in D'_b} L_{\text{uni}}(f(x; \theta)) \\ &= \frac{1}{\sum_{i=1}^{|D'_b|} w_i} \sum_{i=1}^{|D'_b|} w_i L_{\text{uni}}(f(x; \theta)) \end{aligned} \quad (81)$$

The optimal parameters  $\theta^*$  are learned as follows:

$$\begin{aligned} \theta^*(w) &= \arg \min_{\theta} L(\theta; D, w) \\ &= \arg \min_{\theta} L_{\text{in}}(\theta; D) + \alpha L_{\text{out}}(\theta; w) \end{aligned} \quad (82)$$

Therefore, an iterating optimization is solved between finding  $\theta^t$  and  $w^t$  at each step by fixing one and solving the optimization problem for the other. At last, the largest values of weights can be selected regarding the dataset's desired size.

#### 6.14 Input Complexity and Out-of-Distribution Detection With Likelihood-Based Generative Models Serrà et al. (2019):

This work further investigated the problem of generative models assigning higher likelihood values to OOD samples. In particular, this work finds a strong tie between the OOD samples' complexity and likelihood values. Simpler input can lead to higher the likelihood value. Fig. 34 shows this phenomenon. Furthermore, another experiment to support the claim is designed in such a way that we start from a random noise, on which a mean average pooling is applied at each step. To preserve the dimension, an upscaling is done after average poolings. Surprisingly, simpler images on which more average poolings are applied to achieve higher likelihoods. Motivated by this, the work proposed to detect OOD samples by accounting for input complexity in combination with likelihood values. Since it is hard to compute the input complexity, the paper instead calculates an upper bound using a lossless compression algorithm Cover & Thomas (2006). Given a set of inputs  $x$  coded with the same bit depth, the normalized size of their compressed versions,  $L(x)$  (in bits per dimension), is used as the complexity measurement. Finally, the OOD score is defined as Eq. 83:

$$S(x) = -l_M(x) - L(x), \quad (83)$$

where  $l_M(x)$  is the log-likelihood of an input  $x$  given a model  $M$ .

Intuitively, considering  $M_0$  as a universal compressor, then  $p(x | M_0) = 2^{-L(x)}$  and Consequently, the OOD score can be defined as follows :

$$S(x) = -\log_2 p(x | M) + \log_2 p(x | M_0) = \log_2 \frac{p(x | M_0)}{p(x | M)} \quad (84)$$

In the cases where a simple OOD sample is fed into the model, the universal compressor  $M_0$  assigns a high probability to it and effectively corrects the high likelihood wrongly given by the learned model  $M$ . Similar interpretation holds for the complex OOD samples too.

Figure 33: The assigned likelihood values of a simple generative model to different datasets when is trained on CIFAR10. As it is obvious, simpler datasets achieve higher values.

### 6.15 Energy-based Out-of-distribution Detection Liu et al. (2020b):

This work proposes using the energy score derived from the logit outputs for OOD detection, and demonstrated superiority over softmax score. Energy-based models map each input  $x$  to a single deterministic point that is called energy LeCun et al. (2006). A set of energy values  $E(x, y)$  could be turned into a density function  $p(x)$  through the Gibbs distribution:

$$p(y | x) = \frac{e^{-E(x,y)/T}}{\int_{y'} e^{-E(x,y')/T}} = \frac{e^{-E(x,y)/T}}{e^{-E(x)/T}} \quad (85)$$

$E(x)$  is called *Helmholtz free energy* and is equal to:

$$E(x) = -T \cdot \log \int_{y'} e^{-E(x,y')/T} \quad (86)$$

In deep networks, by considering  $E(x, y) = -f_y(x)$ , one can express the free energy function in terms of the denominator of the softmax activation:

$$E(x; f) = -T \cdot \log \sum_i^K e^{f_i(x)/T} \quad (87)$$

The paper also shows that cross-entropy loss facilitates pulling down the energy for in-distribution data during the training process. Moreover, softmax scores can be analyzed through an energy-based perspective, as Eq. 88 shows. During the optimization,  $E(x; f)$  is forced to be small for in-distribution samples while being shifted by  $f^{\max}(x)$  to satisfy the maximum function. Consequently, this results in a biased scoring function that is not suitable for OOD detection.

$$\begin{aligned} \max_y p(y | x) &= \max_y \frac{e^{f_y(x)}}{\sum_i e^{f_i(x)}} = \frac{e^{f^{\max}(x)}}{\sum_i e^{f_i(x)}} \\ &= \frac{1}{\sum_i e^{f_i(x) - f^{\max}(x)}} \\ \implies \log \max_y p(y | x) &= E(x; f(x) - f^{\max}(x)) \\ &= E(x; f) + f^{\max}(x) \end{aligned} \quad (88)$$

Energy score is hyperparameter-free, easy to compute and achieves strong performance compared to the softmax score. Beyond post hoc OOD detection, the paper further demonstrated that energy score can be

utilized for model regularization. Different from outlier exposure which forces the uniform softmax distribution for outlier training samples, energy-based regularization directly optimizes the energy gap between ID and OOD:

$$\begin{aligned} \min_{\theta} E_{(x,y) \sim D_{\text{in}}^{\text{train}}} [-\log F_y(x)] + \lambda \cdot L_{\text{energy}} \\ L_{\text{energy}} = E_{(x_{\text{in}}, y) \sim D_{\text{in}}^{\text{train}}} [\max(0, E(x_{\text{in}}) - m_{\text{in}})^2] \\ + E_{x_{\text{out}} \sim D_{\text{out}}^{\text{train}}} [\max(0, m_{\text{out}} - E(x_{\text{out}}))^2] \end{aligned} \quad (89)$$

The optimization results on stronger performance than OE. At the test time, OOD samples are detected based on a threshold on  $-E(x; f)$ .

Figure 34: The energy-based OOD detection framework. The energy function maps the logit outputs to a scalar through a convenient `logsumexp` operator. Test samples with lower energy are considered ID and vice versa.

### 6.16 Likelihood Regret: An Out-of-Distribution Detection Score for Variational Autoencoder Xiao et al. (2020):

Previous works showed that VAEs can reconstruct OOD samples perfectly, resulting in the difficulty in detecting OOD samples. The average test likelihoods of VAE across different datasets have a much smaller range than PixelCNN Oord et al. (2016) or GlowKingma & Dhariwal (2018), showing that distinguishing between OOD and inlier samples is much harder in VAE. The reason might be because of different ways they model the input distribution. Auto-regressive and flow-based methods model their input at pixel level, while the bottleneck structure in VAE forces the model to ignore some information. To address this issue, a criterion called *likelihood regret* is proposed. It measures the discrepancy between a model trained to maximize the average likelihood of a training dataset, for instance, a simple VAE, and a model maximizing the likelihood of a single input image. The latter is called an ideal model for each sample. Intuitively, the likelihood difference between the trained model and the ideal one might not be high; however, this does not hold for OOD inputs. Suppose the following optimization is performed to train a simple VAE :

$$(\phi^*, \theta^*) \approx \arg \max_{\phi, \theta} \frac{1}{n} \sum_{i=1}^n L(x_i; \theta, \tau(x_i, \phi)), \quad (90)$$

where  $\phi$  and  $\theta$  are the parameters of encoder and decoder respectively, and  $\tau(x_i, \phi)$  denotes the sufficient statistics  $(\mu_x, \sigma_x)$  of  $q_\phi(z | x)$ . For obtaining the ideal model, we can fix the decoder part and solve an optimization problem on  $\tau(x_i, \phi)$  such that its individual ELBO is maximized:

$$\hat{\tau} = \arg \max_{\tau} L(x; \theta^*, \tau) \quad (91)$$

Finally, the likelihood regret is defined as follows:

$$\text{LR}(x) = L(x; \theta^*, \hat{\tau}(x)) - L(x; \theta^*, \phi^*) \quad (92)$$

The optimization of Eq. 91 could be started from the initial point that encoder produces for each input, and a threshold is used on LR values at the test time.

### 6.17 Understanding Anomaly Detection With Deep Invertible Networks Through Hierarchies of Distributions and Features Schirrneister et al. (2020):

This work studied the problem of flow-based generative models for OOD detection. It was noted that local feature such as smooth local patches can dominate the likelihood. Consequently, smoother datasets such as SVHN achieves higher likelihoods than a less smooth one like CIFAR-10, irrespective of the training dataset. Another exciting experiment shows the better performance of a fully connected network than a convolutional Glow network in detecting OOD samples using likelihood value. This again supports the existence of a relationship between local statistics like continuity and likelihood values. Fig. 35 shows the similarity of different dataset local statistics that are computed based on the difference of a pixel value to the mean of its  $3 \times 3$  neighboring pixels.

Figure 35: (A) shows the distribution of local pixel value differences. As it can be seen, distributions are highly overlapped. (B) Likelihoods extracted from the local pixel value differences correlate with CIFAR10-Glow likelihoods.

Furthermore, let us call the summation of the likelihood of pixel value differences computed in a local  $3 \times 3$  neighboring pixels using a histogram with 100 equally distanced bins pseudo-likelihoods. A strong Spearman correlation is found between the pseudo-likelihoods and the exact values of likelihoods, supporting the above assumptions. To address this problem, the following three steps are used:

- Train a generative network on a general image distribution like 80 Million Tiny Images
- Train another generative network on images drawn from the in-distribution, e.g., CIFAR-10
- Use their likelihood ratio for OOD detection

Also, to improve the efficacy, the following outlier loss, which uses OOD samples, can be added to the maximum likelihood objective function:

$$L_o = -\lambda \cdot \log \left( \sigma \left( \frac{\log(p_g(x)) - \log(p_{in}(x))}{T} \right) \right), \quad (93)$$

where  $\sigma$  is sigmoid function.

### 6.18 Self-Supervised Learning for Generalizable Out-of-Distribution Detection Mohseni et al. (2020):

In this work, a self-supervised learning method is employed to use the information of an unlabeled outlier dataset such that the OOD detection utility of an in-distribution classifier is improved. To do so, at first, the

classifier is trained on in-class training samples until the desired performance is achieved. Then, additional outputs (a set of  $k$  reject classes) are added to the last layer. Each training batch consists of ID data and some outlier samples. The following loss function is used:

$$\begin{aligned} & \min(E_{P_{\text{in}(\hat{x}, \hat{y})}}[-\log(P_{\theta}(y = \hat{y} | \hat{x}))]) \\ & + \lambda E_{P_{\text{out}(x, \text{target})}}[-\log(P_{\theta}(y = \text{target} | x))], \end{aligned} \quad (94)$$

where the target is selected based on the following rules:

$$\begin{aligned} & \text{if } \arg \max(P_{\theta}(x)) \in k \text{ then} \\ & \quad \text{target} \leftarrow \arg \max(P_{\theta}(x)) \\ & \text{else} \\ & \quad \text{target} \leftarrow \text{random}(k) \end{aligned} \quad (95)$$

This is similar to unsupervised deep k-means in Caron et al. (2018). If an unlabeled sample in the outlier dataset resembles in-class samples, it is assigned a random reject class each time; otherwise, it is assigned to a specific reject class. This helps unlabeled inliers to be separated from outliers. At the test time, the sum of the softmax output of the OOD classes is used as the detection score.

### 6.19 SSD: A Unified Framework for Self-Supervised Outlier Detection Sehwal et al. (2021):

This work has a very similar idea to GDFR (*c.f.* Section 5.8). It incorporates SSL methods so to alleviate the need for labeling in-class samples. This is different from several aforementioned methods that require solving a classification task. As a result, SSD can be flexibly used in different settings such as ND, OSR, and OOD detection. The main idea is to employ the contrastive learning as in Chen et al. (2020b), and learns semantically meaningful features. After representation learning, a k-means clustering is applied to estimate class centers with mean and covariance ( $\mu_m, \Sigma_m$ ). Then for each test time sample, the Mahalanobis distance to the closest class centroid is used as the OOD detection score:

$$s_x = \min_m (z_x - \mu_m)^T \Sigma_m^{-1} (z_x - \mu_m) \quad (96)$$

The contrastive learning objective function is simple. Using image transformations, it first creates two views of each image, commonly referred to as positives. Next, it optimizes to pull each instance close to its positive instances while pushing away from other images, commonly referred to as negatives:

$$L_{\text{batch}} = \frac{1}{2N} \sum_{i=1}^{2N} -\log \frac{e^{u_i^T u_j / \tau}}{\sum_{k=1}^{2N} I(k \neq i) e^{u_i^T u_j / \tau}}, \quad (97)$$

where  $u_i = \frac{h(f(x_i))}{\|h(f(x_i))\|_2}$  is the normalized feature vector,  $(x_i, x_j)$  are positive pairs for the  $i$ th image from a batch of  $N$  images, and  $h(\cdot)$  is the projection head. Moreover, when a few OOD samples are available, the following scoring function can be used:

$$\begin{aligned} s_x &= (z_x - \mu_{\text{in}})^T \Sigma_{\text{in}}^{-1} (z_x - \mu_{\text{in}}) \\ & - (z_x - \mu_{\text{ood}})^T \Sigma_{\text{ood}}^{-1} (z_x - \mu_{\text{ood}}) \end{aligned} \quad (98)$$

This framework can be extended to the supervised settings when the labels of in-class distribution are available. SSD employs the supervised contrastive learning objective proposed in Khosla et al. (2020):

$$L_{\text{batch}} = \frac{1}{2N} \sum_{i=1}^{2N} -\log \frac{\frac{1}{2N_{y_i}-1} \sum_{k=1}^{2N} I(y_k = y_i) e^{u_i^T u_j / \tau}}{\sum_{k=1}^{2N} I(k \neq i) e^{u_i^T u_j / \tau}}, \quad (99)$$

where  $N_{y_i}$  is the number of images with label  $y_i$  in the batch.

## 6.20 MOOD: Multi-level Out-of-distribution Detection Lin et al. (2021):

This work first investigated the computational efficiency aspect of OOD detection. Intuitively, some OOD samples can be detected using only low-level statistics without any need for complex modelings. To this end, multiple intermediate classifiers are trained, operating at different depths of a trained network, as Fig. 36 shows. To find the desired existing depth, an approximation of the input complexity is needed. To address this issue, similar to Serrà et al. (2019), the number of bits used to encode the compressed image  $L(x)$  is employed. Consequently, exit depth  $I(x)$  is determined based on the complexity range a sample belongs to:

$$I(x) = \min(\lceil L_{\text{normalized}}(x) \times K \rceil, K), \quad (100)$$

where  $K$  is the number of classes.

The OOD scoring function is defined similarly to Liu et al. (2020b), using an energy function on logits as follows:

$$E(x; \theta_i) = -\log \sum_{j=1}^C e^{f_i^{(j)}(x; \theta_i)}, \quad (101)$$

where  $C$  is the number of classes of in-distribution data, and  $f_i^{(j)}(x; \theta_i)$  is the logit output corresponding to class  $j \in 1, 2, \dots, C$  for the intermediate classifier at exit  $i$ . The mentioned criterion has different scales at different depths; therefore, it is normalized as:

$$E_{\text{adjusted}}(x; \theta_i) = -E(x; \theta_i) - \mathbb{E}_{x \in D_{\text{in}}}[-E(x; \theta_i)] \quad (102)$$

Finally, OOD samples are detected based on simple thresholding on the energy score of the desired depth.

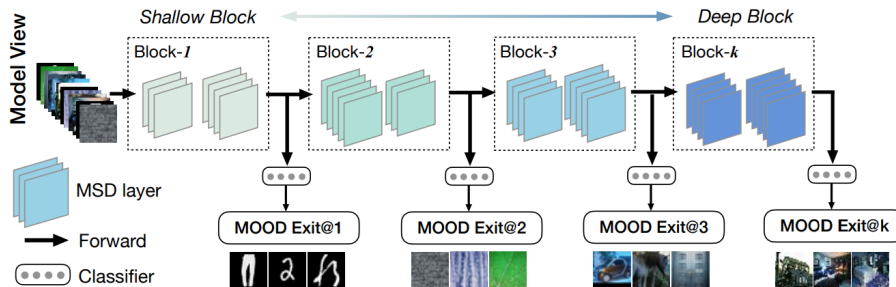

Figure 36: The overall architecture of MOOD. As the figure shows, some OOD samples can be detected by applying simple low-level computations, as opposed to some others that need more complex modelings. Test time computations can be done dynamically and on demand, which significantly reduces computational cost.

## 6.21 MOS: Towards Scaling Out-of-distribution Detection for Large Semantic Space Huang & Li (2021):

MOS first revealed that the performance of OOD detection can degrade significantly when the number of in-distribution classes increases. For example, analysis reveals that a common baseline’s average false positive rate (at 95% true positive rate) would rise from 17.34% to 76.94% as the number of classes increases from 50 to 1,000 on ImageNet1k. To overcome the challenge, the key idea of MOS is to decompose the large semantic space into smaller groups with similar concepts, which allows simplifying the decision boundaries between known vs. unknown data. Specifically, MOS divides the total number of  $C$  categories into  $K$  groups,  $G_1, G_2, \dots, G_K$ . Grouping is done based on the taxonomy of the label space if it is known, applying k-means using the features extracted from the last layer of a pre-trained network or random grouping. Then the standard groupwise softmax for each group  $G_k$  is defined as follows:

$$p_c^k(x) = \frac{e^{f_c^k(x)}}{\sum_{c' \in G_k} e^{f_{c'}^k(x)}}, c \in G_k \quad (103)$$

where  $f_c^k(x)$  and  $p_c^k(x)$  denote output logits and the softmax probability for class  $c$  in group  $G_k$ , respectively. Fig. 37 shows the overall architecture. The training loss function is defined as below:

$$L_{GS} = -\frac{1}{N} \sum_{n=1}^N \sum_{k=1}^K \sum_{c \in G_k} y_c^k \log(p_c^k(x)) \quad (104)$$

where  $y_c^k$  and  $p_c^k$  represent the label and the softmax probability of category  $c$  in  $G_k$ , and  $N$  is the total number of training samples.

A key component in MOS is to utilize a category **others** in each group, which measures the probabilistic score for an image to be unknown with respect to the group. The proposed OOD scoring function, Minimum Others Score (MOS), exploits the information carried by the **others** category. MOS is higher for OOD inputs as they will be mapped to **others** with high confidence in all groups, and is lower for in-distribution inputs. Finally, test time detection is done based on the following score:

$$S_{\text{MOS}}(x) = -\min_{1 \leq k \leq K} (p_{\text{others}}^k(x)) \quad (105)$$

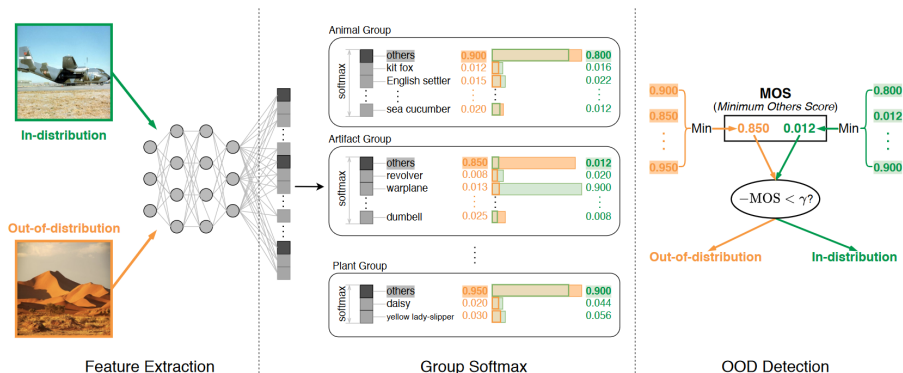

Figure 37: The overall architecture of MOS. As the figure shows, each sample is labeled as "others" for groups to which it does not belong, except the correct group. At the test time, detection is done based on the minimum of "others" class scores.

## 6.22 Can Multi-Label Classification Networks Know What They Don't Know? Wang et al. (2021):

In this work, the ability of OOD detectors in the multi-label classification setting was investigated. In the multi-label classification setting, each input sample might have one or more corresponding labels, which make the problem harder since the joint distribution across labels can be intractable to model. This work proposes the *JointEnergy* criterion as a simple and effective method, which estimates the OOD indicator scores by aggregating label-wise energy scores from multiple labels. Also, they show that JointEnergy can be mathematically interpreted from a joint likelihood perspective. Similar to what has been discussed in Liu et al. (2020b)  $P(y_i = 1 | x)$  can be written as  $\frac{e^{-E(x, y_i)}}{e^{-E(x)}}$ , then by defining *label-wise free energy* that is a special case of  $K$ -class free energy with  $K = 2$ :

$$E_{y_i}(x) = -\log(1 + e^{f_{y_i}(x)}) \quad (106)$$

JointEnergy can be defined as:

$$E_{\text{Joint}}(x) = \sum_{i=1}^K -E_{y_i}(x) \quad (107)$$

Through derivations, the JointEnergy can be decomposed into three terms:

$$E_{\text{joint}}(x) = \log p(x \mid y_1 = 1, \dots, y_K = 1) + (K - 1) \cdot \log p(x) + Z \quad (108)$$

where the first term takes into account joint likelihood across labels; and the second term reflects the underlying data density, which is supposed to be higher for in-distribution data  $x$ . The summation overall results in stronger separability between ID and OOD. The architecture overview is provided in Fig. 38.

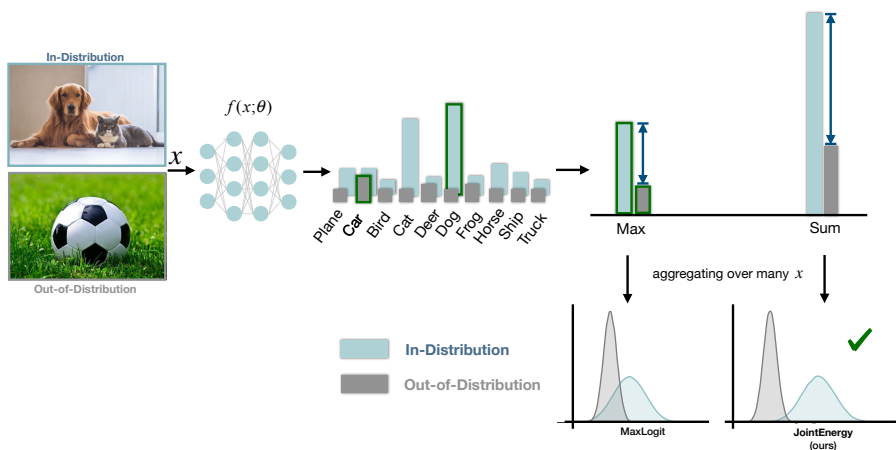

Figure 38: An overview of JointEnergy for OOD detection in multi-label classification networks. During inference time, input  $x$  is passed through a classifier, and label-wise scores are computed for each label. OOD indicator scores are either the maximum-valued score (denoted by green outlines) or the sum of all scores. Taking the sum results in a larger difference in scores and more separation between in-distribution and OOD inputs (denoted by red lines), resulting in better OOD detection. Plots in the bottom right depict the probability densities of MaxLogit versus JointEnergy.

### 6.23 On the Importance of Gradients for Detecting Distributional Shifts in the Wild Huang et al. (2021) :

This work proposes a simple post hoc OOD detection method GradNorm, which utilizes the vector norm of gradients with respect to weights, backpropagated from the KL divergence between the softmax output and a uniform probability distribution. The GradNorm is generally higher for in distribution (ID) data than that for OOD data. Therefore, it can be used for OOD detection. Specifically, the KL divergence is defined as follows:

$$D_{\text{KL}}(\mathbf{u} \parallel \text{Softmax}(f(x))) = -\frac{1}{C} \sum_{c=1}^C \log \left( \frac{e^{f_c(x)/T}}{\sum_{j=1}^C e^{f_j(x)/T}} \right), \quad (109)$$

where  $\mathbf{u}$  is the uniform distribution, and  $C$  is the number of in-distribution classes. Then, the OOD score is defined as  $S(x) = \left\| \frac{\partial D_{\text{KL}}}{\partial W} \right\|_p$  where  $W$  can be (1) a block of parameters, (2) all parameters, and (3) last layer parameters. It was mentioned that the third approach is better than other ones and achieves significant results.

## 6.24 ReAct: Out-of-distribution Detection With Rectified Activations Sun et al. (2021): (R1)

The internal activations of neural networks are examined in depth in this study, and it is discovered that they have considerably different signature patterns for OOD distributions, which can generalize successfully to varied network architectures and OOD detection scores. The distribution of activations in the penultimate layer of ResNet-50, which is trained on the ImageNet, is depicted in Fig. 39. Each point on the horizontal axis represents a single unit of measurement. The mean and standard deviation are depicted by the solid line and shaded area, respectively, on the graph. The mean activation for the ID data (blue) is well-behaved, with a mean and standard deviation that are both nearly constant. Contrary to this, when looking at the raw OOD data (gray), the mean activation shows substantially greater variations across units and is biased towards having sharp positive values. The unintended consequence of having such a high unit activation is that it can present itself in the output of the model, resulting in overconfident predictions on the OOD data. Other OOD datasets exhibit a similar distributional property, which is consistent with previous findings. Therefore, a technique called Rectified Activations (also known as ReAct) is presented as a solution to this problem, in which the oversized activation of a few selected hidden units can be attenuated by rectifying the activations at an upper limit  $c > 0$ . It is demonstrated that ReAct can generalize effectively to a variety of network designs and that it is compatible with a variety of OOD detection methods, including MSP Hendrycks & Gimpel (2016), ODIN Liang et al. (2017), and energy score Liu et al. (2020b), among others.

Figure 39: a) The distribution of ID and OOD uncertainty scores before truncation when ImageNet and iNaturalist are used as in-class and out-of-distribution samples, b) the distribution of per-unit activations in the penultimate layer for ID and OOD data, and c) the distribution of OOD scores after rectification for the ID and OOD data are depicted in the plots above. When ReAct is used, it significantly enhances the separation of the ID and OOD information.

## 7 Dataset

### 7.1 Semantic-Level Datasets

Below we summarize datasets that can be used to detect semantic anomalies. Semantic anomalies are those kinds of anomalies that the variation of pixels leads to the change of semantic content. Datasets such as MNIST, Fashion-MNIST, SVHN, and COIL-100 are considered as toy datasets. CIFAR-10, CIFAR-100, LSUN, and TinyImageNet are hard datasets with more variations on color, illumination, and background. Finally, Flowers and Birds are fine-grained semantic datasets, which makes the problem even harder.

**MNIST LeCun & Cortes (2010):** This dataset includes  $28 \times 28$  grayscale handwritten digits from 0-9 and consists of 60k training images and 10k testing ones.

**Fashion MNIST Xiao et al. (2017):** This dataset comprises of  $28 \times 28$  grayscale images of 70k clothing items from 10 categories. The training set has 60k images and the test set has 10k images.

**CIFAR-10 Krizhevsky et al. (2009):** The CIFAR-10 has 60k natural images. It consists 32x32 RGB images of 10 classes, There are 50k training images and 10k test images.

**CIFAR-100 Krizhevsky et al. (2009):** This dataset is very similar to CIFAR-10, but it has 100 classes containing 600 images each. The 100 classes are grouped into 20 super classes. each class has 500 training images and 100 testing images.

**TinyImageNet Deng et al. (2009):** The Tiny ImageNet dataset consists of a subset of ImageNet images . It contains 10,000 test images from 200 different classes. Also, two more datasets, TinyImageNet (crop) and TinyImageNet (resize) can be constructed, by either randomly cropping image patches of size  $32 \times 32$  or downsampling each image to size  $32 \times 32$ .

**LSUN Yu et al. (2015):** The Large-scale Scene UNDERstanding dataset (LSUN) has a testing set of 10,000 images of 10 different scene categories such as bedroom, kitchen room, living room, etc. Similar to TinyImageNet, two more datasets, LSUN (crop) and LSUN (resize), can be reconstructed by randomly cropping and downsampling the LSUN testing set, respectively.

**COIL-100 Nene et al. (1996):** COIL-100 is a dataset of colorful images of 100 objects. It comprises 7200  $128 \times 128$  images. Images are captured from objects placed on a motorized turntable against a black background, and there are 72 images of each object in different poses.

**SVHN Netzer et al. (2011):** SVHN can be seen as similar in flavor to MNIST (e.g., the images are of small cropped digits), but incorporates an order of magnitude more labeled data (over 600,000 digit images) and comes from a significantly harder, unsolved, real-world problem (recognizing digits and numbers in natural scene images). SVHN is obtained from house numbers in Google Street View images.

**Flowers Nilsback & Zisserman (2008):** Flowers is a 102 category dataset, consisting of 102 flower categories. The flowers chosen to be flower commonly occurring in the United Kingdom. Each class consists of between 40 and 258 images. The images have large scale, pose and light variations. In addition, there are categories that have large variations within the category and several very similar categories.

**Birds Welinder et al. (2010):** CUB-200-2011 is a bird classification task with 11,788 images across 200 wild bird species. There is roughly equal amount of train and test data. It is generally considered one of the most challenging datasets since each species has only 30 images for training.

## 7.2 Pixel-Level Datasets

In these datasets unseen samples, outliers or anomalies do not have semantic difference with inliers. This means an area of the original image is defected; however, the original meaning is still reachable, yet has been harmed.

**MVTec AD Bergmann et al. (2019):** This dataset is an industrial dataset, it provides 5354 high-resolution images divided into ten objects and five texture categories. it contains 3629 training images. test set contains 467 normal images and 1258 abnormal images having various kinds of defects.

**PCB Huang & Wei (2019):** PCB dataset containing 1386 images with 6 kinds of defects for the use of detection, classification and registration tasks. Images are captured in high-resolution.

**LaceAD Yan et al. (2021):** LaceAD contains 9,176 images from the top 10 lace fabric manufacturing companies worldwide, where the images are captured in the real production environment by a high-resolution DSLR camera, They are categorized into 17 subsets based on their patterns. Each image has the size of  $512 \times 512$  and has been labeled by professional workers.

**Retinal-OCT Kermany et al. (2018):** This consists of 84,495 X-Ray images in 4 categories CNV, DME, DRUSEN, and NORMAL, each of which has subtle differences with respect to others.

**CAMELYON16 Bejnordi et al. (2017):** Detecting metastases of lymph nodes is an extremely important variable in the diagnosis of breast cancers. Tissue with metastasis may differ from healthy one only by texture, spatial structure, or distribution of nuclei, and can be easily confused with normal tissue. The

training dataset of Camelyon16 consists of 110 whole-slide images (WSIs) contained tumors, and 160 are not, and testing dataset with 80 regular slides and 50 slides containing metastases.

**Chest X-Rays Wang et al. (2017); Irvin et al. (2019); Rajpurkar et al. (2017):** Chest X-Ray datasets are medical imaging datasets which comprises a large number of frontal-view X-ray images of many unique patients (collected from the year of 1992 to 2015). The datasets include eight to fourteen common disease labels, mined from the text radiological reports via NLP techniques. Images are not registered and captured in different pose and contrast, which makes the detection task challenging.

**Species Hendrycks et al. (2020):** This dataset consists of organisms that fall outside ImageNet-21K. Consequently, ImageNet-21K models can treat these images as anomalous.

**ImageNet-O Hendrycks et al. (2021c):** ImageNet-O is a dataset of adversarially filtered examples for ImageNet out-of-distribution detectors. To create this dataset, at first, ImageNet-22K is downloaded, and shared examples from ImageNet-1K are deleted. With the remaining ImageNet-22K examples that do not belong to ImageNet-1K classes, examples that are classified by a ResNet-50 as an ImageNet-1K class with a high confidence are kept. Finally, visually clear images are selected. This creates a dataset of OOD examples that are hard for a ResNet-50. These examples are challenging for other models to detect, including Vision Transformers.

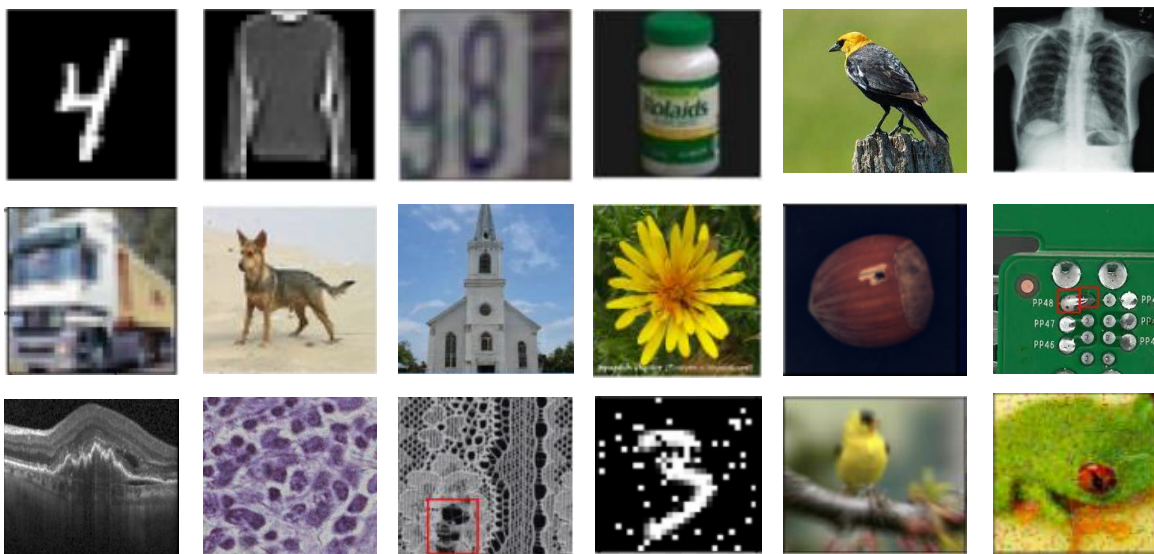

Figure 40: Sample visualization of MNIST, Fashion-MNIST, SVHN, COIL-100, Birds, Chest X-Rays, Cifar-10, TinyImageNet, LSUN, Flowers, MVTEC-AD, PCB, Retinal-OCT, CAMELYON16, LaceAD, MNIST-C, ImageNet-C, and ImageNet-P.

### 7.3 Synthetic Datasets

These datasets are usually made using semantic-level datasets; however, the amount of pixel-variations is under control such that unseen, novel, or abnormal samples are designed to test different aspects of trained models while preserving semantic information. For instance, MNIST-c includes MNIST samples added different kinds of noises such as shot noise and impulse noise, which are random corruptions that may occur during the imaging process. These datasets could be used to not only test the robustness of our models, but also for training models in the AD setting instead of novelty detection or open-set recognition. Due to the lack of comprehensive research in the field of anomaly detection, these datasets can be very beneficial.

**MNIST-C Mu & Gilmer (2019):** MNIST-C dataset is a comprehensive suite of 15 corruptions applied to the MNIST test set for benchmarking out-of-distribution robustness in computer vision. Through several experiments and visualizations, it is shown that the corruptions significantly degrade the performance of state-of-the-art computer vision models while preserving the semantic content of the test images.

**ImageNet-C, ImageNet-P Hendrycks & Dietterich (2019):** This can be seen as the ImageNet version of MNIST-C. For the ImageNet-C, a set of 75 common visual corruptions are applied on each image, and for the ImageNet-P, a set of perturbed or subtly differing ImageNet images are introduced. It is shown that although these perturbations are not chosen by an adversary, currently existing networks exhibit surprising instability on common perturbations.

An overall visualization of the mentioned datasets can be found in Fig. 40.

## 8 Evaluation Protocols

### 8.1 AUC-ROC

Receiver Operating Characteristics (ROC) is a well-known criterion. Given a test dataset including positive and negative (or seen and unseen ) samples, it characterizes the relation between the false positive rate (FPR) and the true positive rate (TPR) at different detection thresholds. AUC-ROC is the area under the ROC curve, which is a threshold-independent metric. The highest value of ROC is 1, and 0.5 indicates a model assigns the positive label with random guessing.

In the literature, AD and ND are usually tested in one-vs-all setting that considers one class as normal and the rest of the classes as anomaly, unseen or unknown. For OOD detection, the in-distribution data is considered as positive and OOD data is considered as negative. For instance, one can train a model on CIFAR-10 and considers MNIST as outlier at the test time. This means training and testing datasets have a large contrast with each other. Sometimes instead of MNIST, uniform noise or Gaussian noise can be used.

### 8.2 FPR@TPR

Although AUC-ROC is a common metric, in practice, models have to select a specific threshold to perform detection. To address this issue, an operating point on the ROC which is desired with respect to applications is selected. A commonly-used metric is FPR@TPR $x$ , which measures the FPR when the TPR is  $x = 0.95$ .

### 8.3 AUPR

AUPR is the Area under the Precision-Recall curve, which is another threshold independent metric. The PR curve depicts the precision= $\frac{TP}{TP+FP}$  and recall= $\frac{TP}{TP+FN}$  under different thresholds. In some literature, the metrics AUPR-In and AUPR-Out denote the area under the precision-recall curve where in-distribution and out-of-distribution images are specified as positives, respectively. This metric is usually used in OOD detection setting.

### 8.4 Accuracy

This metric is usually used in OSR, which is a common choice for evaluating classifiers under the closed-set assumption, as follows:

$$A = \frac{\sum_{i=1}^C (TP_i + TN_i)}{\sum_{i=1}^C (TP_i + TN_i + FP_i + FN_i)} \quad (110)$$

This can be easily extended to open-world assumption in which UUCs must be classified correctly:

$$A_O = \frac{\sum_{i=1}^C (TP_i + TN_i) + TU}{\sum_{i=1}^C (TP_i + TN_i + FP_i + FN_i) + (TU + FU)} \quad (111)$$

Although accuracy is a common metric; however, it is very sensitive to imbalanced number of samples, which is not the case in metrics such as AUC-ROC. To cope with this issue, a normalized accuracy (NA), which weights the accuracy for KKC (AKS) and the accuracy for UUC (AUS) is defined as follows:

$$\text{NA} = \lambda_r \text{AKS} + (1 - \lambda_r) \text{AUS} \quad (112)$$

where

$$\begin{aligned} \text{AKS} &= \frac{\sum_{i=1}^C (TP_i + TN_i)}{\sum_{i=1}^C (TP_i + TN_i + FP_i + FN_i)} \\ \text{AUS} &= \frac{TU}{TU + FU} \end{aligned} \quad (113)$$

and  $0 \leq \lambda_r \leq 1$  is a regularization constant.

## 8.5 F-measure

The F-measure or F-score is the harmonic mean of precision  $P$  and recall  $R$ :

$$F = 2 \times \frac{P \times R}{P + R} \quad (114)$$

Note that  $F$  must be computed in the same way as the multi-class closed set scenario. This is because the correct classifications of UUCs would be considered as true positive classifications; however, it makes no sense since there is no UUC sample in the training process. Therefore, the computations of Precision and Recall only for KKC are modified to give a relatively reasonable F-measure for OSR. The new measures are called macro-F-measure and micro-F-measure respectively as follows:

$$\begin{aligned} P_{\text{ma}} &= \frac{1}{C} \sum_{i=1}^C \frac{TP_i}{TP_i + FP_i}, & R_{\text{ma}} &= \frac{1}{C} \sum_{i=1}^C \frac{TP_i}{TP_i + FN_i} \\ P_{\text{mi}} &= \frac{\sum_{i=1}^C TP_i}{\sum_{i=1}^C (TP_i + FP_i)}, & R_{\text{mi}} &= \frac{\sum_{i=1}^C TP_i}{\sum_{i=1}^C (TP_i + FN_i)} \end{aligned} \quad (115)$$

Note that although the precision and recall only consider the KKC; however, by computing  $FN_i$  and  $FP_i$  false UUCs and false KKC are taken into account Júnior et al. (2017).

## 8.6 Comparing Evaluating Procedures of Each Domain (R1)

Each domain assessment process establishes the practical restrictions that must be met before the claimed performance of proposed methods within that domain can be trusted. Furthermore, in some domains, such as OSR and OOD detection, highlighting the differences in evaluation protocols utilized in each domain might help to gain a better expectation about the reported performances when applied in practical applications. As a result, given an arbitrary dataset such as CIFAR-10 Krizhevsky et al. (2009), the following training/testing setup is employed at each domain :

**AD/ND :** (1) Select a random class out of given 10 classes as normal distribution. (2) Train a one-class feature extractor according to the discussed approaches. (3) Test the trained feature extractor on the entire test-set, which implies the implicit assumption of 10% likelihood for the occurrence of normal events and 90% for the abnormal ones.

**OOD Detection :** (1) Use the whole training dataset to train a multi-class feature extractor. (2) As the out-of-distribution dataset, choose another dataset, such as one of the datasets listed above. (3) Consider

the entire test set to be normal and select some random samples from the out-of-distribution dataset so that the chance of abnormal occurrences is lower than normal when all the samples are combined. As can be observed, this assessment methodology makes an implicit assumption about the rarity of anomalies, which OSR does not.

**OSR :** (1) As the normal distribution, pick  $K$  random classes. (2) Train a multi-class feature extractor according to the discussed approaches. (3) Test the trained feature extractor on the entire test-set. As previously stated,  $K$  is decided based on the **openness score**. This suggests that abnormal events may have a higher probability than normal events, because anomaly means not being a member of the normal sets. For instance, in the self-driving car application, a model might be only responsible for detecting people and cars as two small sets of many definable sets existing in the agent environment. This is a key distinction between the OOD detection and OSR viewpoints.

## 9 Future Challenges

Here we provide plausible future directions, which might be of interest to both practitioners and academic researchers.

### 9.1 Evaluating Baselines and the Evaluation Protocols of OOD Detection

The evaluation protocols for OOD detection has room for improvement. For instance, Ahmed & Courville (2020) trains a mixture of three Gaussians on the CIFAR-10 dataset (as ID), and evaluated against OOD datasets including TinyImagenet (crop), TinyImagenet (resize), LSUN, LSUN(resize) and iSUN. The model is trained channel-wise at a pixel-level. Tab. 2 shows the detection results on different datasets. The results are comparable with SOTA despite the simplicity. In particular, LSUN performs poorly since the majority of them have uniform color and texture, with little variation and structure. Similar to what has been observed in likelihood-based methods, LSUN “sits inside” CIFAR-10 with a similar mean but lower variance, and ends up being more likely under the wider distribution.

We also provide a better insight into the performance of OOD detection baselines, evaluated on both near and far out-of-distribution datasets. For model trained on CIFAR-10, we use CIFAR-100 as the near OOD datasets. The results are presented in Tables 3, 4, and 6. As it is shown, none of the methods are good at detecting both near and far OOD samples, except OE approaches that use an extra auxiliary dataset to do the task. Using Mahalanobis distance can improve the performance of most of the methods at detecting far OOD samples, while degrading the performance of near OOD detection. Besides, as it can have poor performance at detecting even some of far OOD samples due to inaccurate Gaussian density estimation. Moreover, its performance varies significantly when OOD dataset is resized or cropped, showing its dependency on low-level statistics. For instance, notice the SVHN column of Table 6. This is in correspondence with what has been shown recently by Ren et al. (2021) on the deficiencies of Mahalanobis distance as well.

One solution to resolve the issue might be applying input pre-processing techniques such as ODIN to alleviate the effect of first and second-order statistics in assigning OOD scores; however, it increases the execution speed by the sum of an extra forward and backward pass during testing. Additionally, techniques such as ensembling or MC-Dropout Gal & Ghahramani (2016) might be slightly better than others on some OOD datasets; yet, they need multiple forward passes, increasing the execution time significantly. For example, the reported MC-Dropout is 40 times slower than a simple MSP. In summary, we encourage future works to evaluate OOD detection on both near and far OOD datasets.

### 9.2 AD Needs to Be Explored More

As mentioned earlier, AD and ND are not completely the same, both historically and fundamentally. An essential and practical category of problems in the real-world application are those that can not be cleaned easily, and consequently, contain different kinds of noises such as, **label noise** or **data noise**. This is the case in complex and hazardous systems such as modern nuclear power plants, military aircraft carriers, air traffic control, and other high-risk systems Hendrycks et al. (2021b). Recently proposed methods in ND

Table 2: The performance of a simple method using only low-level features on different datasets Ahmed &amp; Courville (2020).

OOD Dataset	Average Precision
TinyImageNet(crop)	96.8
TinyImageNet(resize)	99.0
LSUN	58.0
LSUN(resize)	99.7
iSUN	99.2

need to be evaluated in AD settings using the proposed synthetic datasets, and new solutions need to be proposed. As the openness score is usually high for AD detectors, having a high recall while providing a low false alarm rate is necessary for their practicality Cvach (2012).

Furthermore, almost all the AD or ND methods are evaluated in the one-vs-all setting. This results in having a normal class with a few distribution modes, which is not a good approximation of real-world scenarios. Therefore, evaluating AD or ND methods in multi-class settings similar to OSR domain while having no access to labels could give a more clear perspective on the practicality of SOTA methods. **Table 7 reports the performance of the most notable works using the standard evaluation protocols explained before. All the results are reported from the main papers. (R1)**

### 9.3 OSR Methods for Pixel-Level Datasets

Almost all the methods existing in OSR are evaluated on semantic datasets. As class boundaries in such datasets usually are far from each other, discriminative or generative methods can model their differences effectively. However, in many applications such as Chest X-ray datasets, variations are subtle. Existing methods can result in poor performance on such tasks. For instance, a model may be trained on 14 known chest diseases. A new disease, for example, COVID-19, may emerge as unknowns. In this case, our model must detect it as a new illness instead of classifying it into pre-existing disease categories. Also, in many clinical applications where medical datasets are gathered, usually, disease images are more accessible than healthy ones; thus, OSR problems must be learned on sickness as our normal images and detect healthy ones as abnormal inputs.

Table 5 shows the performance of a simple MSP baseline on MVTECAD dataset when some frequent faults are considered as normal classes. In such scenarios, the goal is to detect and classify well-known faults while distinguishing rare ones as outliers that need to be treated differently. Although this is a common and practical industrial setting, the baseline does not perform better than random, casting doubt on their generality for safety-critical applications.

Recently, Cheng & Vasconcelos (2021) has shown the effectiveness of using a prior Gaussian distribution on the penultimate layer of classifier networks, similar to what has been done in several before-mentioned works, in tasks in which the distribution of seen classes are very similar to each other, for instance, Flowers or Birds datasets that introduced in the previous sections. However, more research should be done in this setting since it is more practical and quite harder than the traditional ones. **Table 8 reports the performance of the most notable works using the standard evaluation protocols explained before. All the results are reported from the main papers. (R1)**

### 9.4 Small Sample Size

Learning with a small sample size is always challenging, but desirable. One way of approaching the problem could be to exploit meta-learning algorithms Finn et al. (2017); Nichol et al. (2018), and to learn generalizable features that can be easily adapted to AD, ND, OSR, or OOD detection using a few training samples Lu et al. (2020). One challenge in meta-learning is handling distribution shift between training and adaptation phase, which might result in producing one-class meta-learning algorithms such as Frikha et al. (2020). Also, other approaches explored generating a synthetic OOD dataset to improve few-shot classification of in-class

samples Jeong & Kim (2020). Although, the combination of meta-learning and AD, ND, OOD detection, and OSR has gained significant attention recently, some important aspects—such as generalizing to detect UUCs using only a few KUC and the convergence of meta-learning algorithms in one-class setting—remain underexplored.

## 9.5 Adversarial Robustness

Carefully designed imperceptible perturbations fooling deep learning-based models to make incorrect predictions are called adversarial attacks Yuan et al. (2019). Up to this time, it has been shown that classifiers are susceptible to adversarial attacks, such that their performance degrades significantly at the test time. As in OOD detection, OSR, AD and ND, being robust against adversarial attacks is crucial. Recent works in OSR Shao et al. (2020); Rozsa et al. (2017), ND Salehi et al. (2021a; 2020), and OOD detection Meinke et al. (2021); Chen et al. (2021) have investigated the effects of adversarial attacks on models; however, more is needed. For instance, as anomalies in AD or UUCs in OSR are inaccessible at the training time, therefore, achieving a robust model on attacked anomalies or UUCs would not be trivial.

The relation of different defense approaches against adversarial attacks with novelty detection can also reveal some important insights about the internal mechanisms of our models. For instance, membership attack Shokri et al. (2017) attempts to infer whether an input sample has been used during the training process or not, which can be seen as designing novelty detectors without having any generalization to UKC samples. Also, Du et al. (2019) investigates the relation of detecting poisoning attacks and novelty detectors. Poisoning examples that are intentionally added by attackers to achieve backdoor attacks could be treated as one type of “outliers” in the training dataset. It is claimed that differential privacy not only improves outlier detection and novelty detection, but also backdoor attack detection of ND models.

From an entirely different point of view, as it is mentioned in Ilyas et al. (2019), adversarial robust training can be employed to boost learned feature space in a semantic way. This path has been followed in ARAE Salehi et al. (2021a) and Puzzle-AE Salehi et al. (2020) to improve the performance of AEs in detecting unseen test time samples. Similar intention is followed in the one-class learning method Goyal et al. (2020) that shows robustness is beneficial for detecting novel samples. This path also needs to be explored more, for instance despite standard adversarial attacks in classification tasks Madry et al. (2017), attacks do not need to be imperceptible anymore in AD or ND and sometimes perceptible ones improve detection performance more.

## 9.6 Fairness and Biases of Models

Research on fairness has witnessed a significant growth recently Zemel et al. (2013); Burrell (2016); Dwork et al. (2012):. It has been shown that models get biased towards some sensitive variables during their training process. For instance, Wang et al. (2020) show that for attribute classification task in the CelebA Liu et al. (2015) dataset, attribute presence is correlated with the gender of people in the image, which is obviously not desirable. Attributes such as gender in the mentioned example are called protected variables. In OOD detection literature, a recent work Ming et al. (2021) systematically investigates how spurious correlation in the training set impacts OOD detection. The results suggest that the OOD detection performance is severely worsened when the correlation between spurious features and labels is increased in the training set. For example, a model that exploits the spurious correlation between the water background and label `waterbird` for prediction. Consequently, a model that relies on spurious features can produce a high-confidence prediction for an OOD input with the same background (i.e., water) but a different semantic label (e.g., boat).

Fairness and AD or ND seems to have fundamental contrast with each other. In fairness, we tend to make unbiased models in which equality constraints between minority samples and majority ones hold while the goal of AD models is to assign higher anomaly scores to rarely happen events. To address this issue Shekhar et al. (2020); Zhang & Davidson (2021) proposed fairness-aware ADs while using the label of protected variables as an extra supervision in the training process.

Table 3: OOD example detection for the maximum softmax probability (MSP) baseline detector, maximum logit value, the MSP detector after fine-tuning with Outlier Exposure (OE), the maximum logit value after fine-tuning with Outlier Exposure (OE), ensemble of 3 models, Mahalanobis distance, and Monte Carlo dropout. Inlier distribution is considered as cifar10. All results are average percentages of 10 runs.

From a different point of view Ye et al. (2021), introduces a significantly important bias in semi-supervised anomaly detection methods such as DSAD Ruff et al. (2019). Suppose DSAD has been implemented in law enforcement agencies to spot suspicious individuals using surveillance cameras. As a few number of training samples has been used as abnormal samples during the process, the trained model might have been biased towards detecting special type of anomalies more than others. For instance, if the auxiliary abnormal training dataset includes more men than women, boundaries of detecting abnormal events as men might be looser than women at the test time. This could also happen in the classification settings such as OOD detection or OSR. Seyyed-Kalantari et al. (2020) reports the existence of unfair biases toward some unrelated protected variables in detecting chest diseases for a classifier trained on Chest X-Ray datasets. From what has been said, it seems fairness and AD, ND, OSR, and OOD detection are strongly correlated because of some critical applications in which they are used and researching more on their correlation is necessary for having practical models.

## 9.7 Multi-Modal Datasets

In many situation, training dataset consists of multi-modal training samples, for instance in Chest-X-Ray datasets, labels of images are found automatically by applying NLP methods on the prescribes of radiologists. In these situations, joint training of different modes could help models to learn better semantic features. However, in this way, models need to be robust in different modes too. For example, in visual Question Answering tasks, we expect our model not to produce any answer for out-of-distribution input texts or images. Note that the correlation between different modes must be attended here, and independent training of AD, ND, OOD detection, or OSR models for different modes results in sticking in local minimas. To cope with this issue, Lee et al. (2020) has explored the performance of VQA models in detecting unseen test time samples. However, there are many more challenges need to be investigated in this way. For instance, the robustness and fairness of VQA OOD models is significantly more challenging compared to single mode datasets, besides due to heavy training process of these models, inventing few-shot methods might be demanding in the fields.

Table 4: OOD example detection for the maximum softmax probability (MSP) baseline detector, maximum logit value, the MSP detector after fine-tuning with Outlier Exposure (OE), the maximum logit value after fine-tuning with Outlier Exposure (OE), ensemble of 3 models, Mahalanobis distance, and Monte Carlo dropout. Inlier distribution is considered as cifar100. All results are average percentages of 10 runs.

## 9.8 Explainability Challenge

Explainable AI (XAI) has found a seriously important role in the recently proposed deep network architectures, especially when they are used in safety-critical applications Arrieta et al. (2020). In AD, OSR, ND and OOD detection due to some of their critical applications, we should be able to explain the reason of decisions our models make Hendrycks et al. (2021a). For instance, if a person is distinguished as suspicious in the surveillance cameras, there must be good reasons for that by which the model has made its decision.

The challenges of explainability can be defined into two different approaches. First, we should explain why a sample is normal, known or in-distribution. Secondly, we should explain why a sample is abnormal, unknown or out-of-distribution. There are a lot of different techniques to explain the decisions of models in the literature such as Grad-cam Selvaraju et al. (2017), Smoothgrad Smilkov et al. (2017), which have been used in Multi-KD Salehi et al. (2021b), CutPaste Li et al. (2021) and Venkataramanan et al. (2020). However, they only have been used to explain normal, seen or in-distribution samples and their results are not as accurate as enough for unseen or abnormal inputs. To cope with the issue, Liu et al. (2020c) proposed a VAE based method which can provide the reasons of abnormality of input samples while performing accurately on explaining normal samples as well. However, it does not work well on complex training datasets such as CIFAR-10, which shows the need of conducting more research toward mitigating the problem.

Another important challenge of explainability can be seen in one-class classification or ND approaches, in which there is only access to one-label at the training time. Therefore, Gradcam or Smoothgrad which use the availability of fine-grain labels can not be used anymore. To address this issue, Liznerski et al. (2020) proposed a fully convolutional architecture with a heatmap upsampling algorithm that is called receptive field upsampling, which starts from a sample latent vector and reverse the effect of applied convolution operators to find important regions in the given input sample. However, explainable OCC models are still largely unexplored and more investigations in this direction are still necessary.

Table 5: OOD example detection for the maximum softmax probability (MSP) baseline detector. Inlier distribution is a set of faults in MVTEC-AD dataset, and outliers are rare faults. All results are average percentages of 10 runs.

Class Name	Normal Sets	AUC	FPR	AUPR
Cable	good, combined, missing cable, poke insulation	51.70	1	24.20
Capsule	good, poke, faulty imprint, crack	56.40	1	15.80
Wood	good, color, scratch, liquid	53.30	1	86.40
Carpet	good, metal, contamination, hole	50.20	1	14.70

## 9.9 Multi-Label OOD Detection and Large-Scale Datasets

While OOD detection for multi-class classification has been extensively studied, the problem for multi-label networks remain underexplored Wang et al. (2021). This means each input has more than one true label by which must be recognized. This is more challenging since multi-label classification tasks have more complex class boundaries, and unseen behaviors could happen in a subset of input sample labels. Another challenge of multi-label datasets can be explored in anomalous segmentation tasks. Different from classification in which one can report an entire image as an abnormal input, the specific anomalous part must be specified here.

Current methods have been primarily evaluated on small data sets such as CIFAR. It’s been shown that approaches developed on the CIFAR benchmark might not translate effectively into ImageNet benchmark with a large semantic space, highlighting the need to evaluate OOD detection in a large-scale real-world setting. Therefore, we encourage future research to evaluate on ImageNet-based OOD detection benchmark Huang & Li (2021), and test the limits of the method developed.

## 9.10 Data Augmentation

One source of uncertainty in classifying known or normal training samples could be the lack of generalization performance. For instance, if one rotates a bird image, its content is not harmed and must be distinguished as the bird again. Some of the mentioned works try to embed this ability into models by designing different SSL objective functions. However, there is also another way to do that, using data augmentations. Data augmentation is a common technique to enrich the training dataset. Some approaches DeVries & Taylor (2017); Zhang et al. (2017); Yun et al. (2019); Hendrycks et al. (2019b); Salehi et al. (2021a) improve generalization performance using different data augmentation techniques.

From another point of view, Pourreza et al. (2021) attempts to generate unseen abnormal samples and use them to convert a one-class learning problem into a simple two-class classification task. Similarly, however in the OSR setting, Kong & Ramanan (2021) and Ditria et al. (2020) follow the same idea. All These works also can be seen as working on a training dataset to make it richer for the further detection task. From what has been said, it is obvious that working on data instead of models could achieve very effective results and must be investigated more in the sense of different trade-offs in the future.

## 9.11 Open-World Recognition

Although detecting novel, unknown or out-of-distribution samples is enough in controlled lab environments, novel categories must be continuously detected and then added to the recognition function in real-world operational systems. This becomes even more challenging when considering the fact that such systems require minimal downtime, even to learn Bendale & Boult (2015). While there has been much research on incremental Rebuffi et al. (2017) and life-long learning Parisi et al. (2019) for addressing the problem of adding new knowledge to a pre-existing one, open-world recognition needs a few more steps. This means

Table 6: OOD example detection for the maximum softmax probability (MSP) baseline detector, maximum logit value (MLV), the MSP detector after fine-tuning with Outlier Exposure (OE), the maximum logit value after fine-tuning with Outlier Exposure (OE), ensemble of 3 models, Mahalanobis distance, and Monte Carlo dropout. Inlier distribution is considered as TinyImageNet. All results are average percentages of 10 runs.

Multiresolution	98.71	94.49	87.18	-	87.74
Contrastive DA	-	94.50	92.40	86.50	86.50

novel classes must be found continuously, and the system must be updated to include these new classes in its multi-class open-set recognition algorithm.

The mentioned process poses many different challenges, from the scalability of current open-set recognition algorithms to designing new learning algorithms to avoid problems such as catastrophic forgetting Rebuffi et al. (2017) of OSR classifiers. Furthermore, all the previously mentioned future works can be reformulated

Table 8: AUROC results of the most notable works for OSR. The performance is averaged across each dataset using the explained evaluation procedures for 10 random trials.(MLS stands for Vaze et al. (2021)).(R1)

Method	MNIST	SVHN	CIFAR-10	CIFAR + 10	CIFAR + 50	TinyImageNet
OpenMax	98.10	89.40	81.10	81.70	79.60	81.10
G-OpenMax	98.40	89.60	67.60	82.70	81.90	58.00
OSRCI	98.80	91.00	69.90	83.80	82.70	58.60
C2AE	98.90	92.20	89.50	95.50	93.70	74.80
CROSR	99.20	89.90	88.30	-	-	58.90
GDFR	-	93.50	80.70	92.80	92.60	60.80
RPL	99.60	96.80	90.10	97.60	96.80	80.90
OpenGan	99.90	98.80	97.30	-	-	90.70
MLS	99.30	97.10	93.60	97.90	96.50	83.00

Table 9: OSR AUROC (R1) results of baselines such as the maximum softmax probability (MSP), Openmax, and CROSR compared to ViT-B16. Known distribution is considered a random selection of 6 classes of the respective datasets and unknown ones are the rest. All results are percentages and the average of 5 runs.

Method	SVHN	MNIST
Softmax	88.60	97.80
Openmax	89.40	98.10
CROSR	89.90	99.10
ViT-B16	82.18	94.89

in open-world recognition problems again, which means by considering a few existing works in these subjects, it needs to be explored more.

## 9.12 Vision Transformers in OOD Detection and OSR

Vision Transformers (ViTs) Dosovitskiy et al. (2020) have recently been proposed to replace CNNs and have shown a great performance in different applications such as object detection Carion et al. (2020), medical image segmentation Valanarasu et al. (2021), and visual tracking Chen et al. (2020a). Similarly, some methods have recently reported the benefits of ViTs in OOD detection Koner et al. (2021); Fort et al. (2021) and have shown their capabilities at detecting near OOD samples. For instance, Fort et al. (2021) has reported the significant superiority of ViTs compared to previous works when they are trained on CIFAR-10 and tested on CIFAR-100 as inlier and outlier datasets, respectively. However, as ViTs usually get pre-trained on extra-large datasets such as ImageNet-22K that has a large intersection with training and testing datasets, the integrity of the train-test mismatch does not hold anymore, and the problem would be converted to “how much does it remember from pretraining”. This means ViTs should be evaluated on datasets that have no intersection with the pre-trained knowledge.

To address this issue, we have evaluated ViT-B16 Dosovitskiy et al. (2020) on SVHN and MNIST when six randomly selected classes are considered as normal and the remaining ones as outliers or unseens. We consider MSP to detect unknown samples. As Table 9 shows, ViT-B16 that is pre-trained on ImageNet-22K is not even as good as other baselines that are trained from scratch. As all the experiments are evaluated in a near OOD detection setting, they support the before-mentioned deficiency of ViTs. From what has been said, a future line of research could be evaluating ViTs in a more controlled situation such that their real benefits would be more precise. Indeed, the recent Species dataset collects examples that do not fall under any of the ImageNet-22K classes and is a first step to rectify this problem Hendrycks et al. (2020).

### 9.13 Identifiability Problems

Providing a method whereby unfamiliar samples are detected is not always trivial. Garg et al. (2021) investigates the theoretical foundations of the problem, demonstrating that determining the accuracy is just as difficult as identifying the ideal predictor, and so the success of any method is dependent on the implicit assumptions about the nature of the shift, which is characterized by mismatches between the source (training) and target (test) distributions. It is demonstrated that no approach of measuring accuracy will work in general without assumptions on the source classifier or the nature of the shift. Average Thresholded Confidence (ATC) is a simple approach for predicting model performance using softmax probability. It learns a threshold for model confidence on the validation source data and predicts the target domain accuracy as the proportion of unlabeled target points with a score greater than the threshold. This work advances the positive answer to the question of a feasible technique for selecting a threshold that enables prediction accuracy with the thresholded model confidence.(R2)

## 10 Conclusion

In many applications, it is not feasible to model all kinds of classes occurring during testing; thus, scenarios existing in domains such as OOD detection, OSR, ND (one-class learning), and AD become ubiquitous. Up to this time, these domains, despite having the same intention and a large intersection, have been followed roughly independently by researchers.

To address the need, this paper gives a comprehensive review on existing techniques, datasets, evaluation criteria, and future challenges. More importantly, we analyzed and discussed the limitations of approaches and pointed out some promising research directions. We hope this helps the research community build a broader and cross-domain perspective.
