

Differentially Private Source-Target Clustering

Anonymous authors

Paper under double-blind review

Abstract

We consider a new private variant of the Source-Target Clustering (STC) setting, which was introduced by de Mathelin et al. (2022). In STC, there is a target dataset that needs to be clustered by selecting centers, in addition to centers that are already provided in a separate source dataset. The goal is to select centers from the target, such that the target clustering cost given the additional source centers is minimized. We consider *private STC*, in which the source dataset is private and should only be used under the constraint of differential privacy. This is motivated by scenarios in which the existing centers are private, for instance because they represent individuals in a social network. We derive lower bounds for the private STC objective, illustrating the theoretical limitations on worst-case guarantees for this setting. We then present a differentially private algorithm with asymptotically advantageous results under a *data-dependent* analysis, in which the guarantee depends on properties of the dataset, as well as more practical variants. We demonstrate in experiments the reduction in clustering cost that is obtained by our practical algorithms compared to baseline approaches.

1 Introduction

Differential Privacy (DP) (Dwork et al., 2006b) is the gold standard for privacy-preservation in data-intensive tasks, defined so as to prevent information about specific individuals from leaking from a dataset. Differential privacy is usually implemented by adding randomness to a computation such that it becomes impossible to determine the specifics of any individual’s data, while still allowing the data to be used for statistical analysis and machine learning tasks. It has been a popular topic of research in the field of machine learning, where researchers have applied its principles to a variety of tasks, including quantile calculation (Kaplan et al., 2022), logistic regression Chaudhuri et al. (2011), principal component analysis (Hardt & Roth, 2013), boosting (Dwork et al., 2010b), support vector machines (Senekane, 2019), and deep learning (Abadi et al., 2016). In this work, we study the application of DP to the problem of *Source-Target Clustering (STC)*.

The STC problem, first introduced by De Mathelin et al. (2022), involves a source dataset S and a target dataset T . The goal is to cluster the target dataset T under the k -medoids cost function. In other words, the goal is to find up to k centers from T , such that the total distance of any point in T from its closest center is the smallest. However, unlike standard k -medoids clustering, in STC all of the data points in S are already selected as centers for “free”, that is, they do not count towards the budget of k centers. Thus, the objective is to select k points from T , such that that the medoids cost over T , when using these points as centers in addition to the points in S , is as small as possible.

In this work, we study a private version of this problem, in which the source dataset S is considered private and the target dataset T is considered public. We would like to achieve the same goal as above, while guaranteeing differential privacy for the source dataset S . In other words, the selection of the k additional centroids from T must be done while preserving the privacy of S .

Applications. Private STC is relevant in any scenario in which an existing set of centers can be used when selecting centers for a target data set, but the selected centers must not violate the privacy of the existing centers. We provide here several concrete examples.

Maximizing influence in a social network. The goal is to find a set of individuals in the network that should be approached to promote a certain message or product. The target dataset T is the set of individuals

that we wish to reach during this promotion, and so we wish to minimize the total distance (in the social network) of each individual from a promoting individual. We have a budget of k individuals that we can approach. In addition, there are individuals in the social network who are already promoting this message or product independently. The set S consists of these individuals. Each of them can be considered a center for the purpose of calculating the cost on T , but their identities should not be leaked, as their participation in the campaign is confidential at this stage. Thus, the choice of users to approach must be done such that the privacy of S is preserved.

Selecting first-aid service locations. The goal is to decide on the location of first-aid service points within a residential area. The target dataset T is the set of geographical locations that need to be covered by first-aid services, and there is a budget of k service locations. However, there are already residents who are on-call paramedics and can be dispatched by authorities to provide first-aid services. The dataset S that lists these residents is not open to the public, and should not be divulged by the choice of additional service locations.

Domain Adaptation. This was the original motivation of de Mathelin et al. (2022) to introduce the original (non-private) STC problem. Domain Adaptation (see, e.g., Nigam et al., 2000; Long et al., 2015) is a setting in which a dataset from a source distribution is available, and we wish to use it to learn a classifier for a target distribution, with the help of a relatively small number of labeled data from the target. De Mathelin et al. (2022) showed that the task of domain adaptation (under certain conditions) can be solved via a reduction to the STC problem. In this case, S is a dataset of points from the source distribution, and T is a dataset of points from the target distribution. k is the budget for labeling examples from T , while it is assumed that all of S is already labeled. De Mathelin et al. (2022) show that by selecting to label the k examples from T that minimize the medoids cost based on taking these k examples and all the examples in S as centers, a target hypothesis can be successfully learned by applying empirical risk minimization to the resulting combined set of labeled examples. Note that STC does not require the labels of S , although in this case they are available.

In this case, private STC is concerned with domain adaptation scenarios in which the dataset S is private. For instance, suppose that a national research institute (NRI) holds a private country-wide labeled medical dataset of patients, while a local pharmaceutical company (PC) wants to train classifiers to predict treatment outcomes for patients in a specific region. PC has an unlabeled medical dataset T that represents the patients in the region, which it is allowed to share with NRI, and the budget to label k of its entries. NRI would thus like to provide PC with a list of examples to label out of T , without breaching the privacy of its own dataset. NRI can use private STC, by setting S to be the list of its private examples, and providing PC with k examples to label from T . The reduction of de Mathelin et al. (2022) implies that *private* domain adaptation can be done using a solution to the private STC problem that we present here, together with a private ERM for minimizing the source risk, of which there are many off-the-shelf solutions.

Summary of contributions. We first formally define the new private formulation of the STC problem (Section 3). We then derive (Section 4) strong lower bounds for private STC (Observation 4.2), showing theoretical barriers on the achievable worst-case guarantees. Having shown the limitations of worst-case guarantees for this setting, we provide (Section 5) algorithms with *data-dependent* guarantees—guarantees that depend on properties of the input data (Theorems 5.5, 5.9, 5.11). We also provide a lower bound that shows that the data-dependent measure that we use in this guarantee is necessary (Observation 5.8). We further present a variant of the algorithm that works better empirically, and demonstrate in experiments (Section 6) its ability to reduce the clustering cost compared to several baselines.

2 Related work

Differentially private clustering has been gaining attention in recent years and various settings have been studied. Feldman et al. (2009) introduced the concept of private coresets, which can be used to reduce the amount of data that needs to be released in order to perform certain types of data analysis. These could potentially be used to privately perform clustering on a subset of the data. Wang et al. (2015) proposed a differentially private algorithm for subspace clustering. Nock et al. (2016) presented a differentially private variant of k -means++, for a setting in which the entire dataset to cluster is private. Su et al. (2016) proposed

a differentially private algorithm for k -means clustering. Feldman et al. (2017) studied the use of coresets for differentially private k -means clustering and its applications in mobile sensor networks. Balcan et al. (2017a) proposed a differentially private algorithm for clustering in high-dimensional Euclidean spaces. Nissim & Stemmer (2018) compared the centralized and local differential privacy models in the context of clustering algorithms. Huang & Liu (2018) presented differentially private algorithms for k -means clustering that have optimal sample complexity and computational complexity. Stemmer & Kaplan (2018) proposed a differentially private algorithm for k -means clustering with a constant multiplicative error. We are not aware of any works that considered the joint private-non-private clustering setting that we study here.

The STC setting was introduced by de Mathelin et al. (2022), motivated by a Domain Adaptation scenario. The setting of Domain Adaptation was first suggested in Nigam et al. (2000). Since then, it has been studied under various scenarios (Sugiyama et al., 2008; Pan et al., 2008; Silva et al., 2012; Shen et al., 2013; Ganin & Lempitsky, 2015) and applied to a variety of applications, such as natural language processing (Blitzer et al., 2007; Ben-David et al., 2006; Jiang & Zhai, 2007; Ramponi & Plank, 2020), speech processing (Leggetter & Woodland, 1995; Gauvain & Lee, 1994; Bacchiani & Roark, 2003; Sun et al., 2017) and computer vision (Martinez, 2002; Xu et al., 2019). In domain adaptation, a classifier is trained on a dataset from a source distribution and then used for prediction on a target distribution. To adapt the model to the target domain when target labels are not available, if a machine learning model is trained on labeled data from one source domain, it may not be able to generalize to new target domains (Saenko et al., 2010). To remedy this problem, unsupervised domain adaptation techniques can be employed (Ganin et al., 2016). It has been shown (see, e.g. Motiian et al., 2017) that incorporating a small amount of labeled data from the target distribution can significantly improve the performance of the classifier.

Several previous works study differentially private domain adaptation. Wang et al. (2020) propose a method for privately adapting deep learning models to new domains using DP. Peterson et al. (2019) study private domain adaptation in the setting of federated learning in which individual private data comes from diverse domains and the goal is to learn a single private shared model. Bassily et al. (2022) studied domain adaptation with a private unlabeled target dataset and a non-private labeled source dataset. This is the mirror image of our setting, in which the source is private and the target is labeled. In addition, there is no attempt to select centers in that work. We are not aware of previous work in which the source dataset is private and needs to be used to select target examples to label.

3 Setting and notation

Assume an example domain \mathcal{X} , equipped with a distance function on \mathcal{X} denoted $\Delta : \mathcal{X} \times \mathcal{X} \rightarrow \mathbb{R}_+$. For an example $x \in \mathcal{X}$ and a (finite) set $S \subseteq \mathcal{X}$, define $\Delta(x, S) := \min_{s \in S} \Delta(x, s)$. Let $\mathcal{S} \in \mathcal{X}^m$ be the private source dataset, and let $\mathcal{T} \in \mathcal{X}^n$ be the target (non-private) dataset. Let T_k denote the set of k selected centers from \mathcal{T} . The cost of the solution T_k is the sum of distances between each point in \mathcal{T} and its closest center in $\mathcal{S} \cup T_k$. Formally, we define

$$\text{Cost}(\mathcal{T}, \mathcal{S}, T_k) := \sum_{x \in \mathcal{T}} \Delta(x, \mathcal{S} \cup T_k) / n.$$

The goal in private STC is to select a set of k points $T_k \in \mathcal{T}^k$ that minimizes this objective function, while preserving the privacy of \mathcal{S} . In this work, we study this problem assuming $\mathcal{X} \subseteq \mathbb{R}^d$ for some integer d and taking Δ to be the Euclidean distance.

We define privacy preservation following the Differential Privacy (DP) framework of Dwork et al. (2006b), which we now recall. Given two databases X, X' of size n from the example domain \mathcal{X} , they are considered *neighbors* under DP if one of them can be obtained from the other by adding or removing a single element. DP is then defined as follows:

Definition 3.1 (Dwork et al. (2006b)). *Let $\epsilon, \delta \geq 0$. Let \mathcal{Y} be an output domain. A randomized algorithm $\mathcal{A} : \mathcal{X}^* \rightarrow \mathcal{Y}$ is (ϵ, δ) -differentially private $((\epsilon, \delta)$ -DP) if for every pair of neighboring databases X, X' and every output subset $Y \subseteq \mathcal{Y}$,*

$$\Pr[\mathcal{A}(X) \in Y] \leq e^\epsilon \cdot \Pr[\mathcal{A}(X') \in Y] + \delta,$$

where the probability is over the randomization of \mathcal{A} . If $\delta > 0$, we say that \mathcal{A} satisfies approximate differential privacy. If $\delta = 0$, we say that \mathcal{A} satisfies pure differential privacy, and that it has ε -differential privacy (ε -DP).

We further study an important recently proposed variant of Differential Privacy, *Zero Concentrated Differential Privacy* (zCDP) (Bun & Steinke, 2016). This formulation offers smoother composition properties than standard (ε, δ) -DP. The general idea is to compare the Rényi divergence of the privacy losses random variables for neighboring databases.

Definition 3.2 (Zero-Concentrated Differential Privacy (zCDP) Bun & Steinke (2016)). *An algorithm $\mathcal{A} : \mathcal{X}^* \rightarrow \mathbb{R}$ is ρ -zCDP if for all neighbouring datasets X, X' and $\alpha \in (1, \infty)$ $\text{RD}_\alpha(\mathcal{A}(Z), \mathcal{A}(Z')) \leq \rho\alpha$, where $\text{RD}_\alpha := \frac{1}{1-\alpha} \log(\int_\omega P(x)^\alpha Q(x)^{1-\alpha} dx)$ is the α -Rényi divergence between random variables A and B .*

In the non-private setting, selecting a set of k points $T_k \in \mathcal{T}^k$ that minimizes the cost function defined above is equivalent to solving a k -medoids problem with a suitable distance function, a problem which is well-studied (see, e.g., Kaufman & Rousseeuw, 2009; Ng & Han, 2002; Park & Jun, 2009). However, this reduction does not preserve the privacy of \mathcal{S} . In the next section, we discuss the hardness of private STC.

4 Lower bounds

In this section, we show that private STC can have a high sensitivity compared to standard DP private clustering, a possible obstacle to DP algorithms. We further provide a lower bound on the **Cost** obtainable by any (ε, δ) -DP algorithm in this setting. From these hardness results, we conclude that any success of a useful algorithm for this setting must be data-dependent.

The property of L_1 -Sensitivity (Dwork et al., 2006b) is crucial for providing guarantees for DP algorithms. A function f mapping databases to \mathbb{R}^w ($w \in \mathbb{N}$) has an L_1 -sensitivity of λ if $\|f(X) - f(X')\|_1 \leq \lambda$ for all pairs $X \in \mathcal{X}^m, X' \in \mathcal{X}^{m-1}$ of neighboring datasets. The L_1 -sensitivity determines the amount of noise that needs to be added to the function to ensure differential privacy (Dwork et al., 2006b; Wang & Chang, 2018). A large sensitivity thus implies that the accuracy of the output could deteriorate significantly in a private setting, unless additional measures are taken. In standard DP clustering (Blum et al., 2005), the entire dataset is private and the goal is to privately select k centers from the domain. The L_1 -sensitivity of the cost function in this case is $2/n$ (assuming the domain is a subset of the unit sphere), where n is the size of the dataset. In contrast, the following observation shows that the sensitivity of the cost function in private STC is constant, and does not become smaller for large datasets.

Observation 4.1 (L_1 -sensitivity of **Cost**). *Let \mathcal{X} be the d -dimensional unit sphere: $\mathcal{X} = \{x \in \mathbb{R}^d : \|x\|_d \leq 1\}$. For any $k \leq \min\{(2\sqrt{d})^d - 1, n/2 - 1\}$, there exists a target dataset $\mathcal{T} \in \mathcal{X}^n$ and a centroid selection $T_k \in \mathcal{X}^k$ such that the L_1 -sensitivity of the function $X \mapsto \mathbf{Cost}(\mathcal{T}, X, T_k)$ is at least $1/4$.*

Proof of Observation 4.1. Since $k+1 \leq (2\sqrt{d})^d$, there exists a set of $k+1$ points such that each pair of them is at least a distance of $1/2$ apart (see, e.g., Conway & Sloane, 2013). Let $x_1, \dots, x_{k+1} \in \mathcal{X}$ be such that $\Delta(x_i, x_j) \geq 1/2$ for all $i \neq j$. Let $\mathcal{T} \in \mathcal{X}^n$ be a dataset that includes x_2, \dots, x_{k+1} and $n-k$ copies of x_1 . Let $\mathcal{S}_1 \in \mathcal{X}^m$ be a dataset that includes x_1 and $m-1$ copies of x_2 . Let $\mathcal{S}_2 \in \mathcal{X}^{m-1}$ be a dataset of size $m-1$, where all points are copies of x_2 . Note that \mathcal{S}_1 and \mathcal{S}_2 are neighbors. For $T_k = \{x_2, \dots, x_{k+1}\}$ we have:

$$|\mathbf{Cost}(\mathcal{T}, \mathcal{S}_1, T_k) - \mathbf{Cost}(\mathcal{T}, \mathcal{S}_2, T_k)| = |0 - \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta(x, \mathcal{S}_2 \cup \mathcal{T})| \geq \frac{1}{2} \cdot \frac{n-k}{n} \geq \frac{1}{4}.$$

This proves the claim. □

Next, we observe that any (ε, δ) -DP algorithm for private STC must incur, with a non-negligible probability, an additive error of $\Omega(1/k)$ relative to the optimal achievable cost using k centers from \mathcal{T} .

Observation 4.2. *Let \mathcal{X} be the d -dimensional unit sphere $\mathcal{X} = \{x \in \mathbb{R}^d : \|x\|_d \leq 1\}$. Let $k \leq (2\sqrt{d})^d - 2$. For any algorithm $\mathcal{A} : \mathcal{X}^* \times \mathcal{X}^* \rightarrow \mathcal{T}^k$ which is (ε, δ) -DP with respect to its second argument, there exist a*

target dataset $\mathcal{T} \in \mathcal{X}^n$ and a source dataset $\mathcal{S} \in \mathcal{X}^m$ such that there is a probability of at least $\frac{1-2\delta}{2e^\epsilon}$ that the output $T_k = A(\mathcal{T}, \mathcal{S})$ satisfies

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) \geq \inf_{\tilde{T}_k \in \mathcal{T}^k} \mathbf{Cost}(\mathcal{T}, \mathcal{S}, \tilde{T}_k) + 1/(2k + 4). \quad (1)$$

where the probability is over the randomness of \mathcal{A} .

The proof is provided in Appendix A. To understand the implications of this observation, note that in DP the values of δ, ϵ may be very small. If, for instance, $\delta, \epsilon \leq 0.1$, Eq. (1) would hold with probability larger than $1/3$. This means that no algorithm for private STC can guarantee an additive error of less than $1/(2k + 4)$ over all datasets. Nonetheless, as we show in Theorem 5.5 and Theorem 5.9 below, by avoiding worst-case analysis and instead deriving a *data-dependent* guarantee, which factors in the properties of the dataset, it is possible to obtain an additive error that does not depend on k , and can be significantly smaller.

5 Algorithms

In this section, we present two algorithms for private STC. Section 5.1 presents an approximate DP algorithm with theoretical guarantees, including a data-dependent cost lower and upper bound which holds with high probability. Section 5.2 presents a practical pure differential privacy algorithm, which is suitable for privacy parameter values commonly used in practice, requiring considerably less added noise. In Section 5.3, we analyse these algorithms also under the zCDP formulation, showing that under this definition the added noise can be reduced even more.

All of the algorithms below use \mathcal{T} and \mathcal{S} to calculate a new privacy-preserving set \mathcal{S}' , which does not violate the privacy of \mathcal{S} . \mathcal{S}' can then be used as input to a (non private) STC algorithm (e.g., de Mathelin et al., 2022) in which \mathcal{T} is the target and \mathcal{S}' is the source dataset. To evaluate the quality of the algorithms' output, it suffices to upper bound the difference in cost between solving (non-private) STC with respect to \mathcal{S}' and solving it with respect to \mathcal{S} . Denote

$$\mathbf{Diff}(\mathcal{S}, \mathcal{S}') := \max_{T_k \in \mathcal{T}^k} |\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) - \mathbf{Cost}(\mathcal{T}, \mathcal{S}', T_k)|.$$

If $\mathbf{Diff}(\mathcal{S}, \mathcal{S}')$ is small, then solving (non-private) STC with respect to (non-private) \mathcal{S}' is almost equivalent to solving it with respect to (private) \mathcal{S} , up to an additive error of $\mathbf{Diff}(\mathcal{S}, \mathcal{S}')$. Thus, we provide guarantees for the algorithms below by upper bounding this quantity.

5.1 An Approximate Differentially Private Algorithm

We propose an (ϵ, δ) -DP algorithm for private STC, named Noisy Average Set (NAS). We assume for simplicity that the domain $\mathcal{X} \subseteq \mathbb{R}^d$ is bounded such that for any $x, x' \in \mathcal{X}$, $\Delta(x, x') \leq 1$. We start by considering a naive approach for using the private dataset \mathcal{S} . For $x \in \mathcal{X}$, denote the nearest neighbor of x in \mathcal{S} by $s_x := s_x^1 := \operatorname{argmin}_{s \in \mathcal{S}} \Delta(x, s)$. Denote the set of the nearest neighbors in \mathcal{S} of the points in \mathcal{T} by $\mathcal{S}^* := \{s_x \mid x \in \mathcal{T}\}$. It suffices to consider the points in \mathcal{S}^* when selecting the best set of centroids in \mathcal{T} . This is made formal in the following observation.

Observation 5.1. *For any $T_k \in \mathcal{T}^k$, $\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) = \mathbf{Cost}(\mathcal{T}, \mathcal{S}^*, T_k)$.*

The proof is provided in Appendix A. Motivated by this simple observation, we aim to design a private algorithm that computes a “sanitized” version of \mathcal{S} , called \mathcal{S}' , hopefully containing points that are close to the points in \mathcal{S}^* . Then, we could solve the problem non-privately using \mathcal{S}' instead of \mathcal{S} . Clearly, due to the DP requirement, we cannot simply copy points from \mathcal{S}^* to \mathcal{S}' . To overcome this, we consider the set of t points closest to x in \mathcal{S} , where $t \in [m]$ is a parameter, and average them in a privacy-preserving manner. NAS, listed in Alg. 1, accepts as input the private source dataset \mathcal{S} , the target dataset \mathcal{T} , the DP parameters ϵ, δ , and a configuration parameter $t \in [m]$. In addition, it uses a provided map $\mathcal{M} : \mathbb{R}^d \rightarrow \mathbb{R}^d$, which needs to have appropriate DP properties, as we discuss below. For every $x \in \mathcal{T}$, Alg. 1 calculates the average of the t points in \mathcal{S} closest to x , where the i 'th nearest neighbor of x in \mathcal{S} is denoted $s_x^i := \operatorname{argmin}_{s \in \mathcal{S} \setminus \{s_x^1, \dots, s_x^{i-1}\}} \Delta(x, s)$. It

Algorithm 1 Noisy Average Set (NAS)

input Private source dataset $\mathcal{S} \in \mathcal{X}^m$, target dataset $\mathcal{T} \in \mathcal{X}^n$, privacy parameters ε and δ , configuration parameter $t \in [m]$, a map $\mathcal{M} : \mathbb{R}^d \rightarrow \mathbb{R}^d$.

- 1: **for** $x \in \mathcal{T}$ **do** $c_x \leftarrow \frac{1}{t} \sum_{i=1}^t s_x^i$ and $s'_x \leftarrow \mathcal{M}(c_x)$.
- 2: $\mathcal{S}' \leftarrow \{s'_x \mid x \in \mathcal{T}\}$
- 3: **return** \mathcal{S}'

then transforms the obtained average c_x using the map \mathcal{M} . Lastly, it returns a privacy-preserving output dataset $\mathcal{S}' \in \mathcal{X}^n$, which includes all transformed averages.

To obtain a DP guarantee for NAS, we set \mathcal{M} to follow the well-known differentially private Laplace mechanism (Dwork et al., 2006b), defined as follows. We say that a random variable is distributed as $\text{Lap}(b)$ if its probability density function is $h(y) = \exp(-|y|/b)/2b$. For a given function $f : \mathcal{X}^t \rightarrow \mathbb{R}^d$ with L_1 -sensitivity λ and for a parameter $b > 0$, the Laplace mechanism gets a tuple of points X and outputs $g(X) := f(X) + \text{Lap}^d(b)$, where $\text{Lap}^d(b)$ is a d -dimensional vector of independent $\text{Lap}(b)$ random variables. The following useful properties of the Laplace mechanism have been shown:

Lemma 5.2 (Dwork et al. 2006b). *The Laplace mechanism is λ/b -DP. In addition, for all $X \in \mathcal{X}^t$, $\gamma \in (0, 1)$, $\Pr[\|g(X) - f(X)\|_\infty > b \cdot \log(d/\gamma)] \leq \gamma$.*

In our case, f is the average function, and we set $\mathcal{M} : \mathbb{R}^d \rightarrow \mathbb{R}^d$ to add the necessary Lap^d noise. We provide the following privacy guarantee for NAS.

Theorem 5.3. *If Alg. 1 runs with \mathcal{M} set as above and $b = \theta(\sqrt{nd \log 1/\delta}/(t\varepsilon))$, then it is (ε, δ) -DP.*

To prove Theorem 5.3, we use the advanced composition property (Dwork et al., 2010a) to aggregate the overall privacy of n application of the subroutine \mathcal{M} . This property states that for all $\varepsilon, \delta \geq 0$ and $\delta' > 0$, the adaptive composition of L algorithms, each of which is (ε, δ) -DP, is $(\tilde{\varepsilon}, \tilde{\delta})$ -DP, where:

$$\tilde{\varepsilon} = \varepsilon \sqrt{2L \ln(1/\delta')} + L\varepsilon \frac{e^\varepsilon - 1}{e^\varepsilon + 1} \quad \text{and} \quad \tilde{\delta} = L\delta + \delta'.$$

Proof of Theorem 5.3. From our assumption that $\Delta(x, x') \leq 1$, the L_1 -Sensitivity of the average function is at most $\frac{\sqrt{d}}{t}$. By Lemma 5.2, each activation of \mathcal{M} is $\theta((n \ln(1/\delta))^{-1/2})$ -DP. Alg. 1 applies the map \mathcal{M} for each $x \in \mathcal{T}$, giving n applications. By the advanced composition property, Alg. 1 is (ε, δ) -DP. \square

Having established the DP properties of Alg. 1, we now provide a data-dependent clustering cost upper bound for its outcome. The bound depends on the data-dependent quantity $\Delta^t(\mathcal{S})$, which we define below.

Definition 5.4. *Denote the average distance between $x \in \mathcal{T}$ and s_x^1, \dots, s_x^t by $\Delta^t(x, \mathcal{S}) = \sum_{i=1}^t \Delta(x, s_x^i)/t$, and let $\Delta^t(\mathcal{S}) = \sum_{x \in \mathcal{T}} \Delta^t(x, \mathcal{S})/n$.*

$\Delta^t(\mathcal{S})$ can be privately calculated using the Laplace mechanism with $b = 1/(t\varepsilon)$. We now use $\Delta^t(\mathcal{S})$ to upper bound $\text{Diff}(\mathcal{S}, \mathcal{S}')$, thus bounding the additive error that results from using \mathcal{S}' instead of \mathcal{S} .

Theorem 5.5. *Suppose that Alg. 1 is run with \mathcal{M} set as above and $b = \theta(\sqrt{nd \log 1/\delta}/(t\varepsilon))$. Then for any $\gamma \in (0, 1)$ Alg. 1 outputs \mathcal{S}' such that with probability $1 - \gamma$,*

$$\text{Diff}(\mathcal{S}, \mathcal{S}') \leq \Delta^t(\mathcal{S}) + \theta\left(\frac{d\sqrt{n \log 1/\delta}}{t\varepsilon}\right) \log\left(\frac{nd}{\gamma}\right).$$

To prove this theorem, we first provide the following lemma, which upper bounds with high probability the absolute difference between $\Delta(s'_x, x)$ and $\Delta(s_x, x)$.

Lemma 5.6. *Suppose that Alg. 1 is run with \mathcal{M} as defined above and $b = \theta(\sqrt{nd \log 1/\delta}/(t\varepsilon))$. Then Alg. 1 outputs \mathcal{S}' such that, with probability at least $1 - \gamma$, for each $x \in \mathcal{T}$,*

$$|\Delta(x, s'_x) - \Delta(x, s_x)| \leq \Delta^t(x, \mathcal{S}) + \theta\left(\frac{d\sqrt{n \log(1/\delta)}}{t\varepsilon}\right) \log\left(\frac{nd}{\gamma}\right).$$

Proof. We consider two cases. In the first case, $\Delta(x, s'_x) \leq \Delta(x, s_x)$. Then

$$\Delta(x, s_x) - \Delta(x, s'_x) \leq \Delta(x, s_x) \leq \frac{1}{t} \sum_{i=1}^t \Delta(x, s_x) \leq \frac{1}{t} \sum_{i=1}^t \Delta(x, s_x^i) = \Delta^t(x, \mathcal{S}).$$

Thus, in this case the bound holds.

In the second case, $\Delta(x, s'_x) \geq \Delta(x, s_x)$. Then, letting $Z \sim \text{Lap}^d(\theta(\frac{\sqrt{nd \log(1/\delta)}}{t\varepsilon}))$, we have

$$\begin{aligned} \Delta(x, s'_x) - \Delta(x, s_x) &\leq \Delta(x, s'_x) \\ &= \Delta(x, c_x + Z) \\ &\leq \Delta(x, c_x) + \|Z\|_2 \\ &\leq \frac{1}{t} \sum_{i=1}^t \Delta(x, s_x^i) + \|Z\|_2 \\ &= \Delta^t(x, \mathcal{S}) + \|Z\|_2 \leq \Delta^t(x, \mathcal{S}) + \sqrt{d}\|Z\|_\infty. \end{aligned}$$

Alg. 1 outputs n d -dimensional random vectors with Laplace distribution with magnitude $\frac{\sqrt{nd \log 1/\delta}}{t\varepsilon}$. By Lemma 5.2, with probability $1 - \gamma$, each such random vector $Z \in \mathbb{R}^d$ satisfies

$$\|Z\|_\infty \leq \theta\left(\frac{\sqrt{nd \log 1/\delta}}{t\varepsilon}\right) \log\left(\frac{nd}{\gamma}\right),$$

Substituting this in the upper bound above gives the statement of the lemma. \square

The proof of this lemma is provided in Appendix A. Next, define $\alpha_x := \text{argmin}_{x' \in \mathcal{S} \cup T_k} \Delta(x, x')$ and $\alpha'_x := \text{argmin}_{x' \in \mathcal{S}' \cup T_k} \Delta(x, x')$. The following lemma uses the lemma above to upper bound the difference between distances to these points.

Lemma 5.7. *Suppose that Alg. 1 is run with \mathcal{M} set as above and $b = \theta(\sqrt{nd \log 1/\delta}/(t\varepsilon))$. Then Alg. 1 outputs \mathcal{S}' such that with probability $1 - \gamma$, for any $T_k \in \mathcal{T}^k$,*

$$|\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)| \leq \Delta^t(x, \mathcal{S}) + \theta\left(\frac{d\sqrt{n \log 1/\delta}}{t\varepsilon}\right) \log\left(\frac{nd}{\gamma}\right).$$

Proof of Lemma 5.7. Suppose that the bound of Lemma 5.6 holds, and fix some $T_k \in \mathcal{T}^k$. Let Λ be the RHS of the upperbound of Lemma 5.6. We consider four cases and show that the bound holds in each.

1. If $\alpha'_x, \alpha_x \in T_k$ then $\alpha_x = \alpha'_x$, hence $|\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)| = 0$.
2. If $\alpha'_x \in \mathcal{S}'$, $\alpha_x \in \mathcal{S}$, then by Lemma 5.6,

$$|\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)| = |\Delta(x, s'_x) - \Delta(x, s_x)| \leq \Lambda.$$

3. If $\alpha'_x \in \mathcal{S}'$, $\alpha_x \in T_k$, then $\Delta(x, \alpha'_x) \leq \Delta(x, \alpha_x) \leq \Delta(x, s_x)$. Therefore,

$$|\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)| \leq \Delta(x, \alpha_x) \leq \Delta(x, s_x) \leq \Delta^t(x, \mathcal{S}).$$

4. $\alpha'_x \in T_k$, $\alpha_x \in \mathcal{S}$:

$$\Delta(x, \alpha_x) = \Delta(x, s_x) \leq \Delta(x, \alpha'_x) \leq \Delta(x, s'_x).$$

Combine with Lemma 5.6 and we get:

$$|\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)| = \Delta(x, \alpha'_x) - \Delta(x, \alpha_x) \leq \Delta(x, s'_x) - \Delta(x, s_x) \leq \Lambda.$$

This completes the proof. \square

To prove Theorem 5.5, observe that by the triangle inequality, $|\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) - \mathbf{Cost}(\mathcal{T}, \mathcal{S}', T_k)| \leq \frac{1}{n} \sum_{x \in \mathcal{T}} |\Delta(x, \alpha'_x) - \Delta(x, \alpha_x)|$. Thus, by Lemma 5.7:

$$\begin{aligned} |\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) - \mathbf{Cost}(\mathcal{T}, \mathcal{S}', T_k)| &\leq \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta^t(x, \mathcal{S}) + \theta \left(\frac{\sqrt{dn \log 1/\delta}}{t\varepsilon} \right) \log \left(\frac{nd}{\gamma} \right) \\ &= \Delta^t(\mathcal{S}) + \theta \left(\frac{\sqrt{nd \log 1/\delta}}{t\varepsilon} \right) \log \left(\frac{nd}{\gamma} \right). \end{aligned}$$

This completes the proof of the theorem. To show that a dependence on $\Delta^t(\mathcal{S})/k$ is necessary, we provide Observation 5.8, a data-dependent variant of Observation 4.2.

Observation 5.8. *Under the same assumptions of Observation 4.2, except that $k \leq (\sqrt{d}/\Delta^t(\mathcal{S}))^d - 2$, it can be shown that with a probability at least $\frac{1-2\delta}{2e^\varepsilon}$,*

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) \geq \inf_{\hat{T}_k \in \mathcal{T}^k} \mathbf{Cost}(\mathcal{T}, \mathcal{S}, \hat{T}_k) + \frac{\Delta^t(\mathcal{S})}{k+2}$$

The proof is identical to that of Observation 4.2, except that the example consists of $k+2$ points that are at least $\Delta^t(\mathcal{S})$ apart, instead of $1/2$ as in the original observation.

5.2 Pure Differentially Private Algorithms

Alg. 1 with the Laplace mechanism parameters defined above satisfies approximate DP. However, its privacy guarantees depend on the value of δ . In practice, it is recommended to use small values of δ to ensure a good level of privacy. This would add an additional constant to the amount of noise injected by the algorithm, which makes it less practical. Therefore, we next introduce two variants of this algorithm which satisfy pure DP. We show in our experiments that these variants work better in practice. The first variant is based on a different parameterization of the Laplace mechanism in Alg. 1. This is provided in the following result, adapted from Theorem 5.3 and Theorem 5.5.

Theorem 5.9 (Alg. 1 Utility with ε -DP). *Suppose we implement \mathcal{M} using the Laplace mechanism with $b = \frac{n\sqrt{d}}{t\varepsilon}$. Then, Alg. 1 is ε -DP and with probability $1-\gamma$ it outputs \mathcal{S}' such that: $\mathbf{Diff}(\mathcal{S}, \mathcal{S}') \leq \Delta^t(\mathcal{S}) + \frac{nd}{t\varepsilon} \log \left(\frac{nd}{\gamma} \right)$.*

To prove this theorem, we use the basic composition property (Dwork et al., 2006a;b), which states that if $\mathcal{A}_1, \dots, \mathcal{A}_k$ are algorithms that satisfy $(\varepsilon_1, \delta_1)$, \dots , $(\varepsilon_k, \delta_k)$ -differential privacy, respectively, then running $\mathcal{A}_1, \dots, \mathcal{A}_k$ satisfies $\left(\sum_{i=1}^k \varepsilon_i, \sum_{i=1}^k \delta_i \right)$ -differential privacy.

Proof of Theorem 5.9. As we saw above, the L_1 -sensitivity of \mathcal{M} is \sqrt{d}/t . Therefore, by Lemma 5.2, each application of \mathcal{A} is ε/n -DP. Since we have n applications of \mathcal{M} , by the basic composition property, Alg. 1 is ε -DP. The cost bound follows analogously to the proof of Theorem 5.5. \square

This obtains pure DP. However, the bound is significantly larger than that of the previous variant, due to the dependence on $O(n)$, instead of the $O(\sqrt{n})$ in Theorem 5.5. This comes hand in hand with added noise of size $O(n)$, which can be prohibitively large in practice. We therefore present an additional pure DP algorithm, called Neighbor Noisy Averages (NNA), which builds on the ideas of NAS but is more practical, and adds noise that does not depend on n at all. In addition, it is parameter-free.

NNA accepts the same inputs as NAS except that it also accepts a confidence parameter γ , and that it requires a map with two arguments. The first argument is used for generating a private count and the second has the same role as the mechanism of NAS. NNA first creates for each $x \in \mathcal{T}$ the set h_x that contains all the points from \mathcal{S} such that x is their nearest point in \mathcal{T} . Next, NNA computes the size of h_x and the sum of its points and uses the mechanism \mathcal{M} to generate a private version of those. Then, it adds the private average of the points to the output \mathcal{S}' only if their private number is larger than a threshold. Note that NNA avoids inserting to \mathcal{S}' averages that include no points, that is cases where $|h_x| = 0$. It can be seen from Lemma 5.2

Algorithm 2 Neighbor Noisy Averages (NNA)

input Source data $\mathcal{S} \in \mathcal{X}^m$, target data $\mathcal{T} \in \mathcal{X}^n$,
 $\gamma \in (0, 1)$, privacy parameter ε ,
a map $\mathcal{M} : \mathbb{R} \times \mathbb{R}^d \rightarrow \mathbb{R} \times \mathbb{R}^d$

- 1: $\mathcal{S}' \leftarrow \{\}$
- 2: **for** $x \in \mathcal{T}$ **do**
- 3: $h_x \leftarrow \{s \in \mathcal{S} \mid x = \operatorname{argmin}_{x' \in \mathcal{T}} \Delta(x', s)\}$
- 4: $n_x, r_x \leftarrow |h_x|, \sum_{s \in h_x} s$
- 5: $\hat{n}_x, \hat{r}_x \leftarrow \mathcal{M}(n_x, r_x)$
- 6: **if** $\hat{n}_x \geq 1 + \log((\sqrt{d} + 1)/\gamma)/\varepsilon$ **then**
- 7: $\mathcal{S}' \leftarrow \mathcal{S}' \cup \{\hat{r}_x/\hat{n}_x\}$
- 8: **end if**
- 9: **end for**
- 10: **return** \mathcal{S}'

Figure 1: An example of a run of NNA. Colors represent points in the sets as given in the legend.

that for the Laplace mechanism used above, with probability $1 - \gamma$, $|\hat{n}_x - n_x| \geq \log((\sqrt{d} + 1)/\gamma)/\varepsilon$ for each $x \in \mathcal{T}$. Therefore, if $n_x \geq 1 + \log((\sqrt{d} + 1)/\gamma)/\varepsilon$, then with probability $1 - \gamma$, h_x contains at least one point.

Figure 1 illustrates the run of NNA with $d = 2$. The key idea behind NNA is that each data point participates in the calculation of a single center, so that each pair of neighboring datasets has the same center distribution, except for one center. As a result, we can avoid using composition. The following theorem shows that NNA is pure DP.

Theorem 5.10. *If Alg. 2 runs with the Laplace mechanism with $b = (\sqrt{d} + 1)/\varepsilon$ then it is ε -DP.*

Proof. Let $\mathcal{S} = \hat{\mathcal{S}} \cup \{\hat{s}\}$ and $\hat{\mathcal{S}}$ be neighboring databases. Let $\hat{x} = \operatorname{argmin}_{x' \in \mathcal{T}} \Delta(x', \hat{s})$, and note that \hat{s} belongs to $h_{\hat{x}}$ and to no other h_x . Therefore, for each $x \neq \hat{x}$ the distribution of the possible outputs \hat{r}_x/\hat{n}_x is the same under \mathcal{S} and $\hat{\mathcal{S}}$. Since $\forall x, x' \in \mathcal{X}, \Delta(x, x') \leq 1$, the sum function used to calculate r_x has an L_1 -sensitivity of \sqrt{d} , and the counting function has an L_1 -sensitivity of 1. Therefore, \mathcal{M} has an L_1 -sensitivity of $\sqrt{d} + 1$. Since \hat{n}_x, \hat{r}_x are obtained from the Laplace mechanism with $b = (\sqrt{d} + 1)/\varepsilon$, by Lemma 5.2 the algorithm satisfies ε -DP. \square

Unlike for NAS, we do not have a cost upper bound for NNA. Nonetheless, we show below that in practice, the latter is more successful than the former, perhaps due to the reduction in added noise.

5.3 Concentrated Differential Privacy

We now study NAS and NNA under the zCDP formulation of Differential Privacy. It is known that DP implies zCDP (Bun & Steinke, 2016). Nonetheless, by tailoring the noise mechanism, we obtain improved zCDP guarantees compared to a naive transformation, which require significantly less noise than the DP formulation. We use the Gaussian mechanism, defined as follows. For a given function $f : \mathcal{X}^t \rightarrow \mathbb{R}^d$ with L_2 -sensitivity λ , the Gaussian mechanism gets a tuple of points X and outputs $q(X) := f(X) + Z$, where Z is a d -dimensional vector of independent $\mathcal{N}(0, \sigma^2)$ random variables. It is known (Bun & Steinke, 2016) that the Gaussian mechanism is $\frac{\lambda^2}{2\sigma^2}$ -zCDP and that in addition, $\Pr[\|q(X) - f(X)\|_\infty \geq \sqrt{2\sigma^2 \log(2d/\gamma)}] \leq \gamma$. We first obtain a guarantee for NAS.

Theorem 5.11 (NAS with zCDP). *Let $\rho > 0$. Suppose we implement \mathcal{M} using the Gaussian mechanism with $\sigma = \frac{1}{t} \sqrt{\frac{n}{2\rho}}$. Then, Alg. 1 is ρ -zCDP. Moreover, with probability $1 - \gamma$, for the output \mathcal{S}' of Alg. 1,*

$$\text{Diff}(\mathcal{S}, \mathcal{S}') \leq \Delta^t(\mathcal{S}) + \frac{1}{t} \sqrt{\frac{nd}{\rho} \log\left(\frac{2nd}{\gamma}\right)}.$$

To prove this theorem, we use the zCDP composition theorem (Bun & Steinke, 2016), which states that for $\mathcal{M} : \mathcal{X}^n \rightarrow \mathcal{Y}$ and $\mathcal{M}' : \mathcal{X}^n \rightarrow \mathcal{Z}$, if \mathcal{M} satisfies ρ -zCDP and \mathcal{M}' satisfies ρ' -zCDP, then the mechanism $\mathcal{M}'' : \mathcal{X}^n \rightarrow \mathcal{Z}$, defined by $\mathcal{M}''(X) = \mathcal{M}'(X, \mathcal{M}(X))$, is $(\rho + \rho')$ -zCDP.

Proof of Theorem 5.11. By our assumption that $\Delta(x, x') \leq 1$, the L_2 -Sensitivity of the Gaussian mechanism we use is $1/t$. Therefore, by the properties of the Gaussian Mechanism, each application of \mathcal{M} is ρ/n -DP. Since we have n applications of \mathcal{M} , by the composition theorem, Alg. 1 is ρ -zCDP. The cost bound is proved analogously to the proof of Theorem 5.5. \square

For NNA, the noise can be a constant that does not depend on d , unlike the standard DP version.

Theorem 5.12 (NNA with zCDP). *Alg. 2 with the Gaussian mechanism with $\sigma = \sqrt{2/\rho}$ is ρ -zCDP.*

Proof. By our assumption that $\Delta(x, x') \leq 1$, the L_2 -Sensitivity of the Gaussian mechanism we use is 2. As in the proof of Theorem 5.10, we can avoid the composition in the applications of \mathcal{M} , each of which is ρ -zCDP. Therefore, Alg. 1 is ρ -zCDP. \square

Thus, with the zCDP formulation the algorithms require less added noise.

6 Experiments

We implemented Alg. 1 in the ε -DP version, as well as Alg. 2. The python code will be made publicly available and is provided in the supplementary material. For Alg. 1, we tested several values of t and got similar results, thus we provide below results for $t = 150$, and report the others in Appendix C.1. As the non-private STC algorithm that is applied to the output \mathcal{S}' , we used the state-of-the-art algorithm Accelerated K-medoids (AkM) (de Mathelin et al., 2022).

Since the noise added by Alg. 1 grows with n (the size of \mathcal{T}) we used a *coreset* to reduce the amount of noise. A coreset (Har-Peled & Mazumdar, 2004) is a subset of a dataset that approximately preserves the properties of the original dataset. By constructing a coreset \mathcal{T}' such that each point in \mathcal{T} is C -close to a point in \mathcal{T}' , we can get the same guarantee as in Theorem 5.9 up to an additive term of C , but with a smaller dependence on the dataset size (see Appendix B for a formal result). We constructed the coresets using Bentley & Friedman (1979) with a termination condition of $C = 0.05$ (see Appendix B for more on the choice of C).

We ran our algorithms on synthetic and real-world datasets, and compared them to the following ε -DP baselines: (1) **ClusterT**: Apply AkM on \mathcal{T} without considering \mathcal{S} ; (2) **DP-GAN** (Xie et al., 2018): This algorithm privately learns a distribution from source data. We trained DP-GAN on the input \mathcal{S} , then drew m i.i.d. samples from the output distribution, and used them as the source for AkM. We used the implementation

Figure 2: The synthetic datasets

and best-practice parameters of Falk & Meneses (2019). (3) `PrivateKmeans` (Balcan et al., 2017b): We privately clustered \mathcal{S} to 100 centers, then used them as input to the AkM algorithm. For the zCDP version of `PrivateKmeans` and `DP-GAN`, we set $\varepsilon = \sqrt{\rho/2}$ to obtain ρ -zCDP (see Bun & Steinke, 2016). In all of the experiments, the points were normalized to have a maximal norm of $1/2$. We fixed $\varepsilon = 3$ for DP and $\rho = 3$ for zCDP. For each dataset, algorithm and k , we averaged $\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k)$ over 30 runs.

We first report results on three simple 2-dimensional synthetic datasets, plotted in Figure 2. These datasets were constructed to highlight the drawbacks of the baseline algorithms, all of which ignore the target data \mathcal{T} . In each of these datasets, a smart choice of centers should avoid selecting target centers in an overlapping region. The datasets are generated as follows:

Synthetic 1 Two 2-dimensional Gaussians with different means. The source data is $\mathcal{S} \sim \mathcal{N}((0.15, 0.15), 0.4)$ and the target data is $\mathcal{T} \sim \mathcal{N}((0.95, 0.95), 0.4)$.

Synthetic 2 \mathcal{S} has 18 clusters on the top and 9 clusters on the bottom right. \mathcal{T} has 9 clusters on the bottom left and 9 clusters on the bottom right. Each cluster is a Gaussian with standard deviation of 0.01.

Synthetic 3 \mathcal{S} is composed of 6 clusters, with means drawn uniformly at random out of $[0, 1] \times [0, 1]$. Each cluster is a Gaussian with standard deviation 0.03. \mathcal{T} has 12 clusters which are also Gaussians with means drawn uniformly at random. Each cluster is a Gaussian with standard deviation 0.01.

The results for the synthetic datasets for standard DP are provided in Figure 3 (top). The results for zCDP are provided in Appendix C.2. It can be seen `PrivateKmeans` and `DP-GAN` perform comparably or worse than the vanilla `ClusterT` that does not use \mathcal{S} at all. This may be because they cluster the entire source data instead of focusing on the parts relevant to \mathcal{T} like our algorithms. In contrast, our algorithms improve over the vanilla approach and their cost is close to that of the non-private STC algorithm. In Appendix C.3, we present ablation studies on coresets usage, demonstrating cost improvements in many cases and no harmful effects. As expected, the effect on NAS is much more significant than the effect on NNA, since the added noise in NAS depends on n , unlike in NNA. We also demonstrate, in Appendix C.6, that the results of the baseline algorithms are not improved by using coresets.

Next, we report experiments on real-world datasets. `MNIST` (Deng, 2012) includes 70,000 grayscale images of handwritten digits. We tested three (source,target) pairs of digits: (1,7), (5,2) and (9, 6). `Office` (Saenko et al., 2010) includes images of office items from different sources: "amazon" (2817 samples), "webcam" (795 samples) and "dslr" (digital single-lens reflex) (480 samples). We tested all (source,target) pairs. `Superconductivity` (Hamidieh, 2018) is an 82-dimensional dataset of 16,000 superconducting materials. Following the domain adaptation setup of Pardoe & Stone (2010), We split the dataset into four subsets termed low (l), middle-low

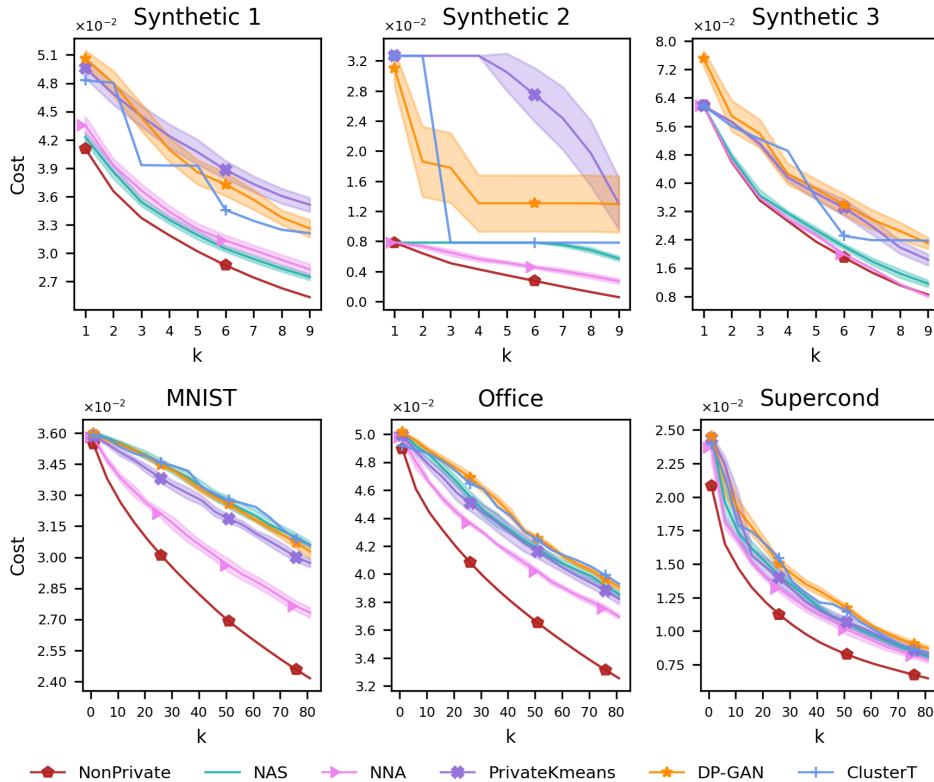

Figure 3: Top: Synthetic DP experiments. Bottom: Real-world DP experiments; MNIST: 6 \mapsto 9, Office: amazon \mapsto webcam, Superconductivity: high \mapsto middle-high

(ml), middle-high (mh) and high (h) of around 4000 instances each. We tested all possible (source, target) pairs.

We applied random dimensionality reduction (Johnson, 1984) with $d = 8$ to all datasets, a privacy-preserving transformation. Fig. 3 (bottom) provides the results of the experiments for DP, for a single (source,target) pair for each dataset. The rest of the pairs, as well as experiments for zCDP, are reported in Sec. C.4 and C.5, respectively. For both privacy formulations, the baselines `PrivateKmeans` and `DP-GAN` perform like the vanilla `ClusterT` that does not use \mathcal{S} at all. In contrast, our algorithms show a significant cost improvement, with the exception of `NAS` in the standard DP setting. This is expected, as discussed in Sec. 5.2, due to the significant added noise required in this case. We further compare, in Sec. C.7, the run-time of all algorithms that maintain source privacy, showing that all algorithms require similar running times.

7 Conclusions

We proposed a new setting of private Source-Target Clustering. We derived lower bounds and data-dependent upper bounds for this objective, proposed two private-STC algorithms, and showed in experiments that they perform significantly better than the baselines. In future work, we hope to study also cases where the target dataset has privacy restrictions.

A Deferred proof

Proof of Observation 4.2. Since $k + 2 \leq (2\sqrt{d})^d$, there exists a set of $k + 2$ points such that each pair of them is at least a distance of $1/2$ apart (see Conway & Sloane (2013)). Let $x_1, \dots, x_{k+2} \in \mathcal{X}$ be such that $\Delta(x_i, x_j) \geq 1/2$ for $i \neq j$. Assume for simplicity that $N = n/(k + 2)$ is an integer. Let \mathcal{T} be a dataset that includes $2N$ copies of x_1 and N copies of each of x_2, \dots, x_{k+1} . Let $\mathcal{S}_1 \in \mathcal{X}^m$ be a dataset that includes x_1 and $m - 1$ copies of x_{k+2} . Let $\mathcal{S}_2 \in \mathcal{X}^{m-1}$ be a dataset that includes only $m - 1$ copies of x_{k+2} . Note that \mathcal{S}_1 and \mathcal{S}_2 are neighbors.

Since \mathcal{S}_1 include x_1 , the (unique) optimal solution is $T'_k = \{x_2, \dots, x_{k+1}\}$, which satisfies $\mathbf{Cost}(\mathcal{T}, \mathcal{S}_1, T'_k) = 0$. Any other solution $T_k \neq T'_k$ satisfies $\mathbf{Cost}(\mathcal{T}, \mathcal{S}_1, T'_k) \geq 1/(2k + 4)$. Therefore, if $\Pr[A(\mathcal{T}, \mathcal{S}_1) = T'_k] \leq 1 - \frac{1-2\delta}{2e^\varepsilon}$, then A incurs an additive error of at least $1/(2k + 4)$, as claimed. We thus henceforth assume that $\Pr[A(\mathcal{T}, \mathcal{S}_1) = T'_k] > 1 - \frac{1-2\delta}{2e^\varepsilon}$.

Consider now the solution for the private dataset \mathcal{S}_2 with the same target dataset \mathcal{T} . Since $T'_k \in \mathcal{T}^k$ does not include x_1 , we have:

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}_2, T'_k) = \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta(x, \mathcal{S}_2 \cup \mathcal{T}) \geq \frac{2N}{n} \cdot \Delta(x_1, \mathcal{S}_2 \cup \mathcal{T}) = 2/(2k + 4).$$

On the other hand, letting $T_k^* = \{x_1, \dots, x_k\}$, we have:

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}_2, T_k^*) = \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta(x, \mathcal{S}_2 \cup \mathcal{T}) = \frac{N}{n} \cdot \Delta(x_{k+1}, \mathcal{S}_2 \cup \mathcal{T}) = 1/(2k + 4).$$

Therefore, whenever $A(\mathcal{T}, \mathcal{S}_2)$ outputs T'_k , an additive error of at least $1/(2k + 4)$ is incurred. Since $\mathcal{S}_1, \mathcal{S}_2$ are neighbors, then due to the (ϵ, δ) -DP of A ,

$$e^{-\varepsilon}(\Pr[A(\mathcal{T}, \mathcal{S}_1) = T'_k] - \delta) \geq e^{-\varepsilon}(1 - \frac{1-2\delta}{2e^\varepsilon} - \delta) \geq e^{-\varepsilon}(1 - \frac{1}{2e^\varepsilon}) - \frac{2\delta}{2e^\varepsilon} \geq \frac{1-2\delta}{2e^\varepsilon}.$$

This lower bounds the probability of an additive error of $1/(2k + 4)$, as claimed. \square

Proof of Observation 5.1. For $x \in \mathcal{T}$, let $\alpha_x := \operatorname{argmin}_{x' \in \mathcal{S} \cup T_k} \Delta(x, x')$. We have:

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) = \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta(x, \mathcal{S} \cup T_k) = \frac{1}{n} \sum_{x \in \mathcal{T}} \Delta(x, \alpha_x) = \frac{1}{n} \sum_{\substack{x \in \mathcal{T} \\ \alpha_x \in \mathcal{S}}} \Delta(x, \alpha_x) + \frac{1}{n} \sum_{\substack{x \in \mathcal{T} \\ \alpha_x \in T_k}} \Delta(x, \alpha_x).$$

For any $x \in \mathcal{T}$ such that $\alpha_x \in \mathcal{S}$, $\alpha_x = s_x \in \mathcal{S}^*$. Therefore,

$$\mathbf{Cost}(\mathcal{T}, \mathcal{S}, T_k) = \frac{1}{n} \sum_{\substack{x \in \mathcal{T} \\ \alpha_x \in \mathcal{S}^*}} \Delta(x, \alpha_x) + \frac{1}{n} \sum_{\substack{x \in \mathcal{T} \\ \alpha_x \in T_k}} \Delta(x, \alpha_x) = \mathbf{Cost}(\mathcal{T}, \mathcal{S}^*, T_k),$$

as claimed. \square

B A Guarantee for Coresets

The following is an immediate Corollary of Theorem 5.5.

Corollary B.1. *Given a coreset $T' \subseteq \mathcal{T}$ for size n' which satisfies $d(x', x) \leq C$ for each $x \in \mathcal{T}, x' \in T'$, every solution $T_k \in \mathcal{T}^k$ satisfies, with probability $1 - \gamma$:*

$$\|\mathbf{Cost}(\mathcal{S}, T_k) - \mathbf{Cost}(\mathcal{S}', T_k)\| \leq \Delta^t(\mathcal{S}) + \theta\left(\frac{d\sqrt{n' \log 1/\delta}}{t\varepsilon}\right) \log\left(\frac{n'd}{\gamma}\right) + C.$$

Note that this corollary shows the natural trade-off between n' and C , as a lower value of C would result in a higher value of n' and vice versa. Note that avoiding coresets altogether is equivalent to taking $C = 0, n' = n$. It is possible to optimize this trade-off using private access to the source dataset, but this would require sacrificing some of the privacy budget. In preliminary experiments, we found that it does not improve the results.

C Full experiment results

C.1 Experiments with other values of t

Figure 4 and Figure 5 report experiments comparing the performance of NAS over different values of t . It can be seen that the results are not very sensitive to the value of t .

C.2 Experiments for zCDP with synthetic datasets

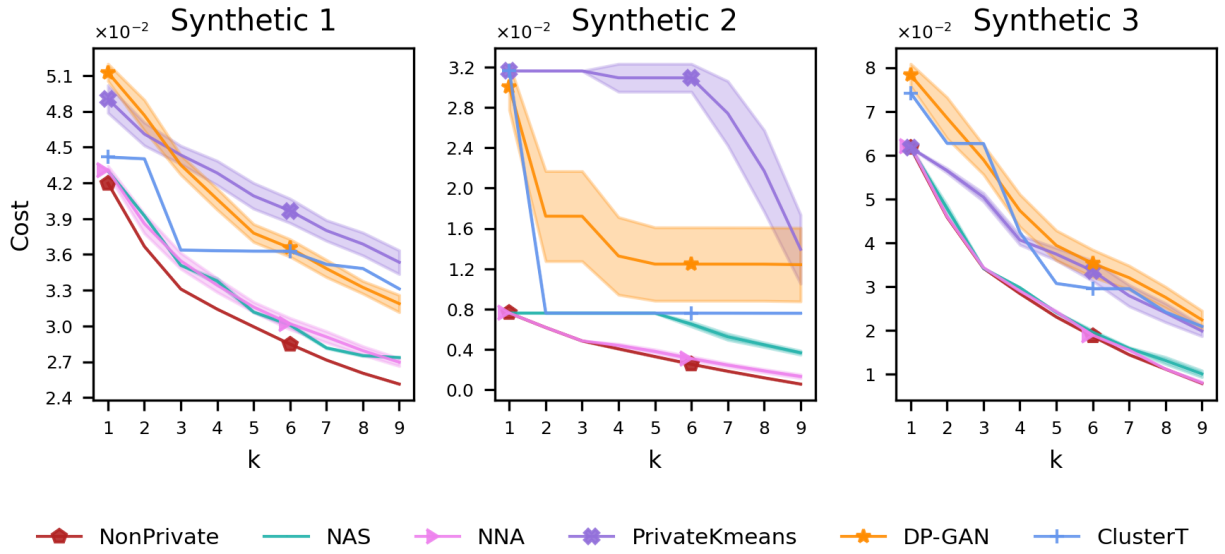

Figure 6: Results of zCDP experiments with synthetic datasets

Figure 7: NAS results of ablation studies for using coresets, synthetic datasets

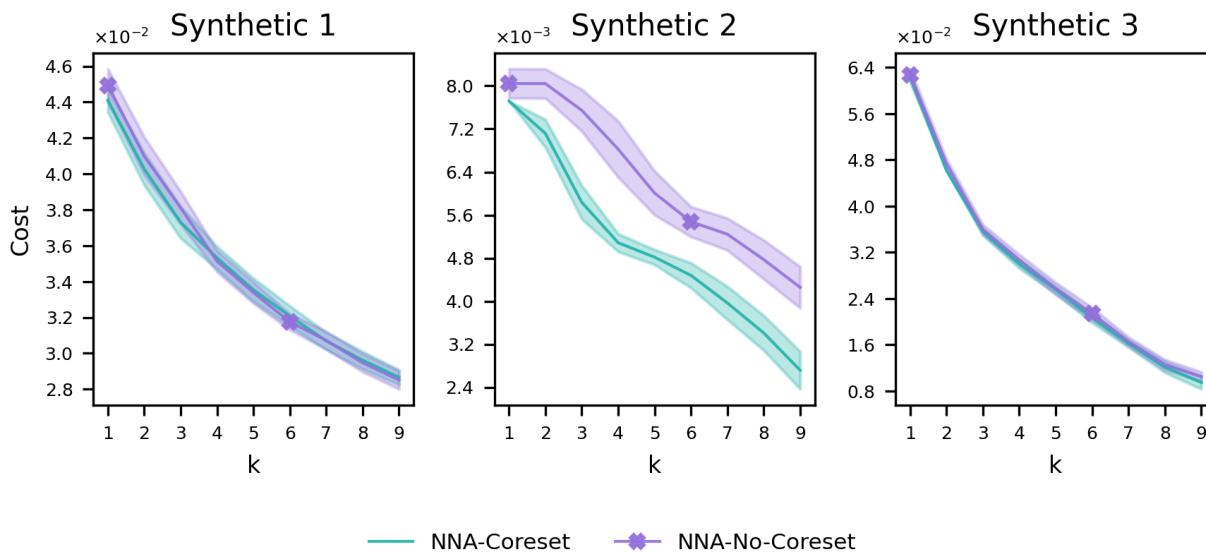

Figure 8: NNA results of ablation studies for using coresets, synthetic datasets

C.3 Coreset ablation experiments

In the following experiments, we report a comparison between using coresets and not using them, for the two algorithms NAS and NNA, and for all the synthetic and real-world datasets that we tested. In all the experiments C was set to 0.05. The synthetic experiments (Figure 7) show that coresets can provide significant improvements. In real-world datasets, coresets were helpful in some of the cases (see Figures 167, 168, 169, 170, 171, 174, 34, 35, 36, 47, 50), while in others there was no observable difference. There was no case in which coresets were harmful.

C.6 The effect of coresets on the baseline algorithms

As discussed in Section 6, using a coreset before clustering \mathcal{T} is helpful for our algorithms, because it reduces the size n of the clustered data, which affects the amount of added noise. In contrast, using coresets for the baseline algorithms is not expected to improve their results, since they gain no benefit from a smaller \mathcal{T} . To verify this, we report experiments comparing the use of the baseline algorithms with and without a coreset.

It can be seen that using the coreset has a negligible effect on the results of the baseline algorithms. This demonstrates that the advantage of our algorithms cannot be achieved solely by using coresets.

C.7 Run time comparison

For each experiment, we report the average running times over 30 runs. All run times were measured when running on one core of an Intel i9-9900K CPU and NVIDIA GEFORCE RTX 2080 Ti GPU. It can be seen that there are no significant differences between the running times of the various algorithms.
