Abstract

Type 2 diabetes (T2D) is a chronic disease currently affecting around 500 million people worldwide and potentially leading to severe health conditions. Yet, the causes for the underlying beta-cell failure leading to impaired insulin secretion are not fully understood, especially on a morphological level. While giga-pixel microscopy images may visualize such subtle morphological differences, the dimensionality and variability of the data quickly surpass the limits of human analysis. In response, we collected a dataset consisting of pancreas whole-slide images stained with multiple chromogenic and multiplex fluorescent stainings and trained various deep learning models to predict the T2D status. Using explainable AI (XAI) methods, we rendered the learned relationships humanly understandable, quantified them as comprehensive biomarkers, and utilized statistical modeling to assess their association with T2D. Our analysis reveals the contributions of adipocytes, pancreatic islets, and fibrotic patterns to T2D.

1 Introduction

Based on the current WHO classification of diabetes, over 90% of all persons with the disease fall into the category defined as type 2 diabetes (T2D). T2D is a major global health issue, affecting millions and placing a significant burden on healthcare systems [1]. Drivers of T2D are insulin resistance and impaired insulin secretion, with dysfunction of pancreatic islet beta-cells being a key feature. Despite extensive research, the exact nature of beta-cell failure in T2D remains unclear. Given the high degree of inter-individual variability, no specific traits are sufficient for pathologists to discriminate whether a pancreatic sample belongs to a subject with or without T2D. Pancreatic tissue, represented in giga-pixel whole-slide images (WSIs), lacks clear features that differ significantly between individuals with and without T2D.

Our goal was therefore to assess whether the exploitation of an imaging data-driven approach combining attention-based DL models with explainable artificial intelligence (XAI) would enable the attribution of a pancreatic patient to a patient with or without T2D with high reliability. While DL models could find patterns in data infeasible to detect by doctors, XAI methods subsequently rendered the learned relationships human-understandable, revealing regions of interest (ROIs) associated with the occurrence of T2D. Given the limited feasibility of qualitative analyses of large amounts of XAI results, we quantified the attention to the ROIs and subsequently computed specific biomarkers for the most important ones. At last, we analyzed these biomarkers in combination with clinical patient data using statistical models. Besides the integration of vast amounts of diverse WSIs, our approach offered the advantage that we do not bias ourselves to prior assumptions regarding T2D as the XAI application can also uncover unanticipated findings, leading to the formulation of new hypotheses about the disease.

2 Classification of T2D from WSIs of pancreatic tissue sections

Dataset We first applied both single chromogenic and multiplex fluorescence techniques to immunostain pancreas sections from 100 patients with (35) or without (65) T2D who underwent pancreatectomy [2–5] at two medical centers. Immunostained antigens included glucagon, insulin, and somatostatin as markers of islet α-, β- and δ-cells, respectively, as well as PECAM1 for endothelial cells (blood vessels), perilipin 1 for adipocytes (fat cells) and tubulin beta 3 for neuronal axons. In the case of the chromogenic stainings, each marker was detected individually in serial sections counterstained with hematoxylin. In the case of multiplex fluorescent stainings, serial sections were incubated with DAPI and primary antibodies either against glucagon, somatostatin, and tubulin beta 3 (Stainingset 1), or against insulin, PECAM1, and perilipin 1 (Stainingset 2) (see Figure 1 (a)). Brightfield and fluorescent WSIs were then used to train DL models distinguishing donors with or without T2D (see Figure 1 (b)). See Appendix A for a full description of the cohort and staining procedures. Patients were split into a training set (75) and a test set (25). For the chromogenic data, where each of the six stainings is available as an individual RGB WSI, separate models per staining were trained. In contrast, the multiplex fluorescent data contained multiple stainings in one WSI via different image channels. We compared different representations of these WSIs by either treating each of the three channels as color channel (RGB), encoding each of the channels individually and
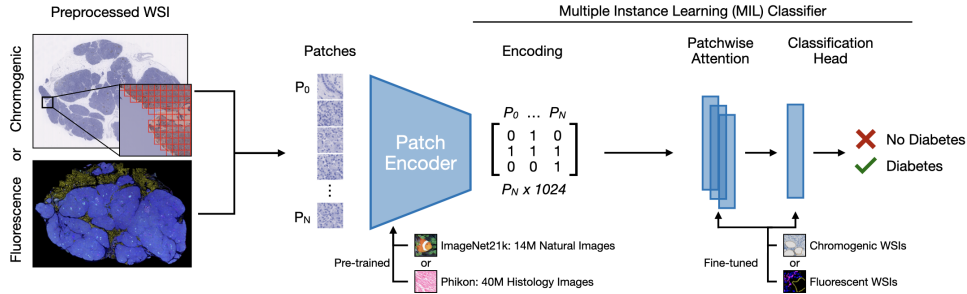

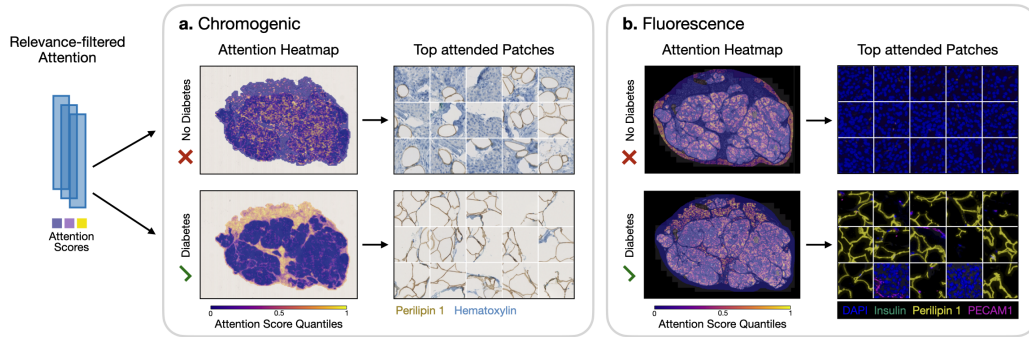

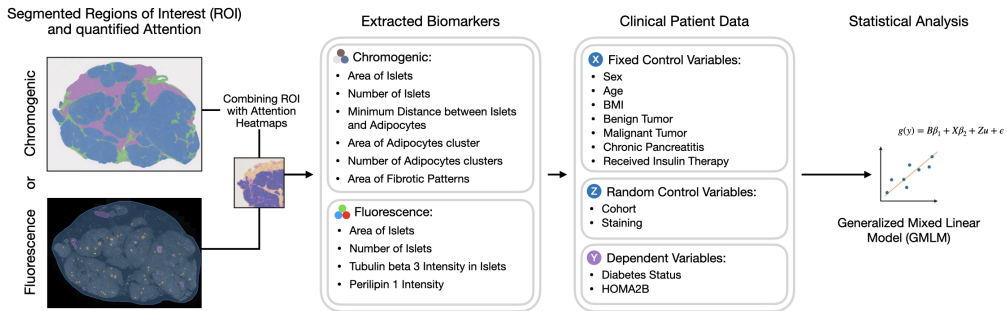

Figure 1: **(A)** We acquired serial pancreatic tissue sections, fasting blood samples, and clinical data from 100 patients. Further, we used six chromogenic stainings for brightfield and two staining sets for multiplex fluorescence microscopy to capture the WSIs. **(B)** Multiple Instance Learning (MIL) architecture with different pretrained encoders and fine-tune MIL classifier. **(C)** XAI methods were used to identify regions of interest (ROIs) utilized by the models for their prediction. **(D)** ROIs were segmented and quantified, with extracted biomarkers and clinical covariates analyzed using statistical models.
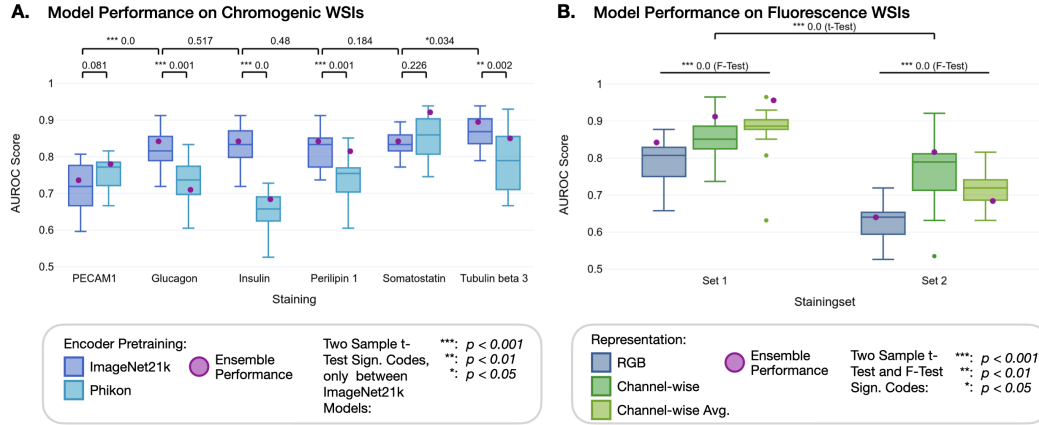

A. Model Performance on Chromogenic WSIs

B. Model Performance on Fluorescence WSIs

Figure 2: Performance efficiency of trained models to predict type 2 diabetes on chromogenic **(A)** and fluorescent **(B)** WSIs. AUROCs show ImageNet21k/CLAM outperforms Phikon/CLAM in most cases, with tubulin beta 3 achieving the highest performance, and Stainingset 1 with channel-wise average representation performing best on fluorescent WSIs.

append all resulting feature vectors (channel-wise) or encoding each of the channels individually and averaging the resulting feature vectors (channel-wise avg).

Model Performance   WSI classification is a multiple instance learning (MIL) problem since an entire image is too large to be processed at once while a classification label is only available globally but not per patch. We used CLAM [6] which first encodes individual patches via a pre-trained feature extractor and then aggregates the features using attention mechanisms followed by a classification layer to obtain the WSI-level prediction. This allows for a direct interpretability of patch importance by visualizing the attention scores over the WSI. See Appendix B for further experiments with other MIL models.   For the chromogenic data we tested two vision transformers either pre-trained on Imagenet21k [7] or Phikon [8], a foundation model trained on thousands of WSIs), while on the fluorescent data we only used Imagenet21k. When applied to chromogenic brightfield WSIs, the ImageNet21k pre-training delivered the best prediction performance on average (AUROC = 0.833; Figure 2 (a) and Appendix Table 3). Across all stainings except for PECAM1 and somatostatin, there was a significant increase in AUROC when using the ImageNet21k pre-trained encoder. When ImageNet21k/CLAM-based prediction was conducted using fluorescent WSIs, Stainingset 1, despite the absence of insulin staining, yielded significantly better classification results than Stainingset 2. The best performance was reached using the channel-wise avg representation on Stainingset 1 (Ensemble AUROC=0.956; Figure 2 (b) and Appendix Table 2).

3   AI models attend to specific biological traits

Upon completion of model training, we aimed to understand the biological features utilized by the models in predicting diabetes. For this purpose, we employed XAI techniques specifically within the domains of Attention and Attribution methods, to highlight regions critical to the models when predicting the T2D status Figure 1 (c). We applied these techniques to the best classification model among the evaluated training settings for both fluorescent and chromogenic modalities.

Initially, we focused on determining the significance of specific patches using the built-in attention mechanism of the multiple instance learning (MIL) classifier and creating attention heatmaps for the individual chromogenic and fluorescent WSIs of each patient Figure 3. The heatmaps of the chromogenic WSIs revealed both similarities and distinctions in the regions important to the model when classifying a WSI to diabetes or its absence. Specifically, for the "diabetes" outcome (Figure 3 (a), lower panels), several stainings showed heightened attention to fibrotic patterns (left side of the PECAM1-, glucagon-, insulin-, and somatostatin-stained WSIs) as well as a pronounced focus on adipocytes (top left of the perilipin 1-stained WSI). Both recognized features, i.e. fibrotic changes and adipocyte infiltration are mainly localized in the exocrine tissue. Notably, in the chromogenic WSIs
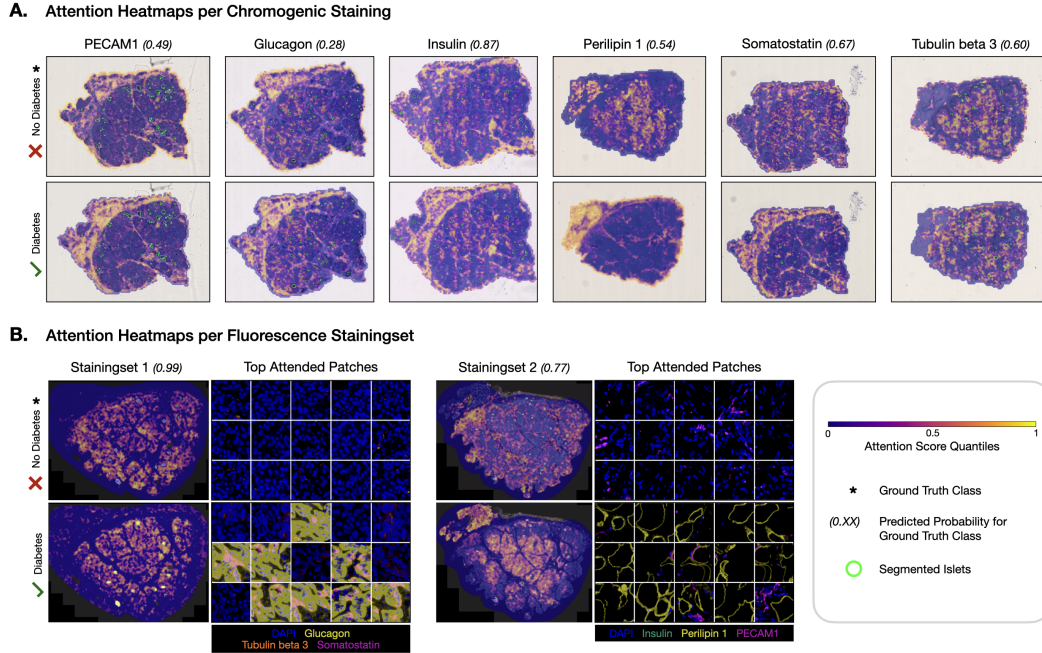

4

Figure 3: Representative attention heatmaps for the chromogenic **(A)** and fluorescent **(B)** WSIs of a single patient. Top 15 attended fluorescent patches associated with T2D or no T2D status.

the fibrotic patterns were revealed by low-intensity diffuse staining of the tissue by diaminobenzidine precipitates, regardless of antigen specificity, accounting for spatially restricted, high-intensity signals. Conversely, for the "no T2D" outcome, the models demonstrate significantly less attention to fibrotic patterns. Instead, they concentrate on tissue borders and display more dispersed attention patterns. The heatmaps for the fluorescent WSI of both Stainingsets revealed similar attention patterns such as on adipocytes (perilipin 1) in Stainingset 2 Figure 3 (b).

While these heatmaps facilitate the visualization of larger ROIs in the tissue, they do not provide detailed insights into the finer biological features that the model considers significant. To address this, we first sampled the top attended patches using attention scores (Figure 3 (b), see Appendix G for chromogenic WSIs), essentially zooming in from image-level to patch-level. In the case of fluorescent WSI, these heatmaps reveal that for Stainingset 2, the model indeed exhibits a high level of attention to adipocytes (perilipin 1). However, for Stainingset 1, the model focuses also on islet α-cells (glucagon), when classifying "diabetes". This focus of the model on α-cells when classifying a patient as having diabetes is not observable from the patch-level heatmap alone.

To further determine the specific pixel-level features utilized by the model in each of the top-attended patches, we employed multiple attribution methods to quantify the contribution of individual pixels to the predicted outcomes. The model was indeed able to recognize biological traits, such as cell nuclei, adipocyte cytosolic compartments, inter-cellular structures, or islets Appendix H. Integrating all XAI findings, we compiled a comprehensive report for each patient, imaging modality, and DL model.

4 Quantifying Attention to regions-of-interests

To quantitatively assess the global importance of specific regions across all heatmaps, we implemented a scalable, data-driven methodology. We examined highly attended patches to determine their corresponding tissue types. Those reoccurring were defined as ROIs and segmented in the WSI using a specifically trained DL segmentation model to enable quantitative analysis of total attention to different relevant tissue types (similar to localization metrics in XAI). The attention scores within ROIs were standardized for tissue size and total amount of attention. Our analysis of the attention scores revealed a heterogeneous distribution of attention toward tissue components such as islets, adipocytes, or fibrotic patterns in the individual chromogenic stainings. Attention to islets showed the highest z-scores for insulin and glucagon-stained WSIs, but it did not depend on diabetes status
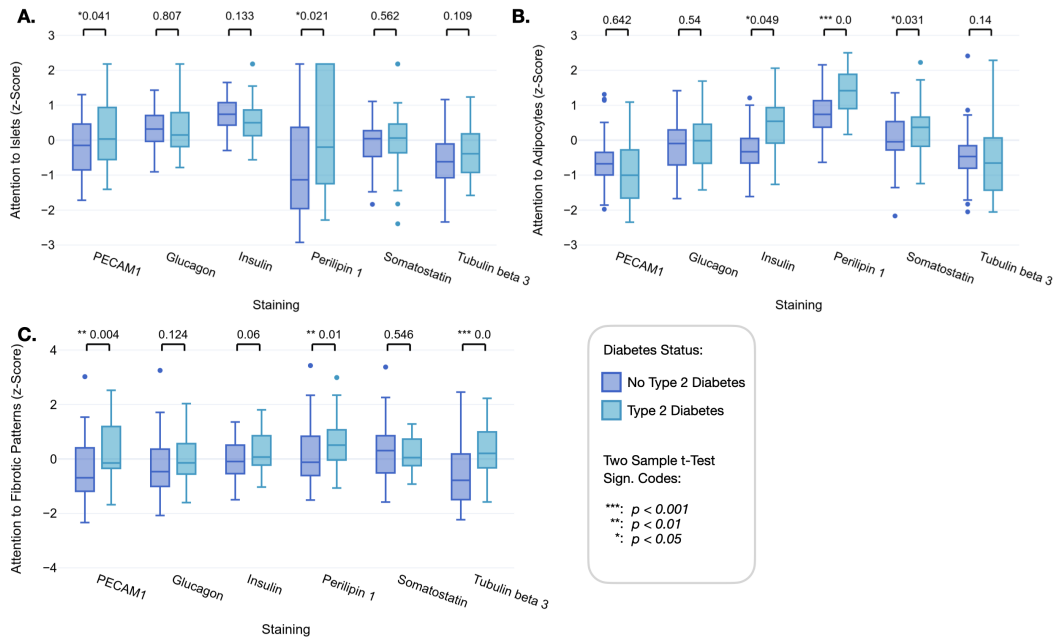

Figure 4: Z-scores for average attributed attention to (A) islets, (B) adipocytes, and (C) fibrosis for the individual chromogenic stainings of patients with and without T2D.

Figure 4 (a). The attention to adipocytes showed significant variability across different stainings, with the highest z-scores for the perilipin 1 staining Figure 4 (b). Notably, regardless of the stained antigens, the model's attention to fibrosis in the chromogenic WSIs was significantly higher in patients with T2D on the PECAM1, perilipin 1 and tubulin beta 3 stainings, indicating its potential relevance in the pathology of the disease Figure 4 (c).

Table 1: Regression results of the generalized mixed linear model analysis for diabetes status (A) and HOMA2B (B) level based on chromogenic.

Based on XAI results and segmentation maps, we computed various imaging biomarkers related to T2D status, noting differences between chromogenic and fluorescence modalities, particularly where certain ROIs, like fibrotic patterns, couldn't be assessed in fluorescent WSIs due to the lack of dedicated staining. To evaluate the impact of these biomarkers on T2D status and insulin secretion (HOMA2B), we used a generalized mixed linear model (GMLM), controlling for patient traits and random effects associated with the cohort and staining method. See Figure 1 (d) for a list of all biomarkers and control variables and Table 1 for the chromogenic results (Appendix I for the fluorescence). Together with the XAI results, we derived the following three main findings:

Amount of Adipocytes affect Islets. The analysis of the chromogenic biomarkers revealed that the area of adipocyte clusters is positively associated with T2D, whereas the number of adipocyte clusters was inversely correlated with the disease (see Table 1 (a)). A higher number of adipocyte clusters may indicate a more advanced adipose infiltration of pancreatic tissue, i.e. intralobular adipocytes [9]. Such an intralobular infiltration would allow the adipocytes to get closer to the islets and thereby impact the islet microenvironment with negative consequences for insulin secretion [10]. Indeed we observe, that for patients with T2D, the pancreatic islets are on average closer located to adipocytes than for patients without T2D (see "Min. Dist. Islets and Adypocytes" Covariate in Table 1).

Fibrosis as a potential structural alteration by T2D. The peroxidase reaction used in chromogenic staining made it possible to see areas rich in extracellular matrix (ECM) within pancreatic tissue, clearly distinguishing between the main tissue structures and the surrounding connective tissue, also reported by de Haan et al. [11]. DL models showed greater attention to these ECM-rich areas in PECAM1 and perilipin 1 stainings when predicting T2D. Our results in Table 1 verify a positive association between the amount of fibrosis and T2D, independent of pancreatic tumors or insulin therapy, highlighting fibrosis as a potential structural alteration in T2D.

Significance of tubulin beta 3 for T2D detection. Chromogenic mono stainings had lower predictive performances than immunofluorescence images, with the highest average performance found for tubulin beta 3, which was also a key component of the best-performing fluorescence Stainingset 1. Notably, tubulin beta 3 and perilipin 1 received higher attention in T2D samples compared to non-T2D WSIs. These findings suggest that alterations in tubulin beta 3 structures may be a distinguishing feature of T2D, potentially impacting islet cell function [12, 13].

6 Conclusion

In this study, we analyzed a unique dataset of human pancreatic WSIs from T2D and non-T2D donors, enabling the training of deep learning models that accurately predict T2D status. This outcome is novel and represents a remarkable advancement in the field of DL-based biomarker discovery, especially because the pancreas, a central organ in the pathophysiology of T2D, exhibits only subtle anatomical changes in this condition, unlike in the case of cancer or pancreatitis. See Appendix F for a discussion of the limitations in the experiment setting. Our XAI-based analysis uncovered biomarkers that support hypotheses about the involvement of adipocytes, pancreatic islets, and enrichment of fibrotic patterns with T2D. This highlights the complexity of T2D pathogenesis and underscores the potential of DL and XAI methods in uncovering novel insights from large-scale microscopy data.

Appendix

A Clinical Cohort

We analyzed clinical, laboratory, and histologic data obtained within the "Studying Islets from Living Donors" (SILDS) programs. Patients undergoing pancreatic surgery for different indications provided written informed consent to donate blood samples and pancreas tissue, and share health records and laboratory data for research purposes at both study sites. We obtained macroscopically healthy tissue resected during surgery but not required for further pathology workup. All patients were of European ethnicity. Additionally, fasting blood was drawn pre-surgery for detailed metabolic phenotyping. Fasting glucose and C-peptide levels were measured as previously described [14], and homeostatic model assessment (HOMA) of insulin secretion was calculated using the computer model-based HOMA-2B [15]. None of the participants had depleted endogenous insulin production as measured by C-peptide-based HOMA2B (lowest HOMA2B: 6% with a diabetes duration of 24 years), excluding type 1 diabetes among the participants. Information on medical history was collected by a physician. Documented by their health records, T2D patients were diagnosed as having T2D at least one year before admission to pancreatic surgery. This excludes diabetes in the context of exocrine pancreatic disease. In contrast, patients without diabetes neither had diabetes nor did they fulfill diagnostic criteria of T2D based on glycated hemoglobin (HbA1c) and fasting glucose, as defined by the American Diabetes Association [16]. Data Acquisition

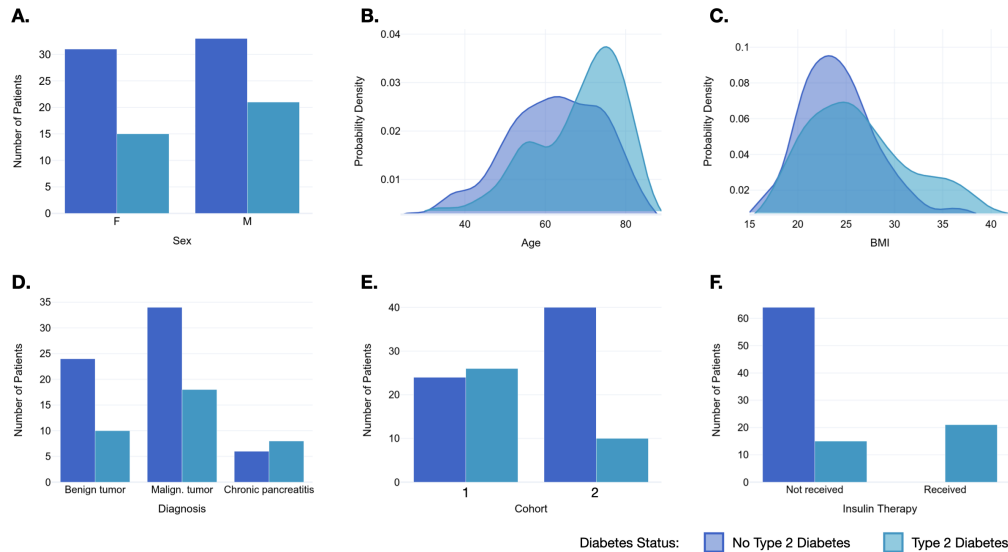

Figure 5: Distribution of Hospital Patient Data. Distribution of all control variables between both T2D statuses, excluding staining: sex (**A**), age (**B**), BMI (**C**), diagnosis of related illness (**D**), cohort (**E**), and insulin therapy (**F**).

Hospital Patient Data. The patient cohort-related metadata are summarized in Figure 5. The quantitative analysis of these parameters in Figure 5 revealed an unbalanced distribution of sex, age, BMI, tumor type, chronic pancreatitis, and cohort between the patients with and without diabetes. In 9 patients, fasting blood samples were not obtained prior to surgery and therefore HOMA2B was not calculated.

Chromogenic immunostaining and brightfield microscopy. Formalin-fixed, paraffin-embedded (FFPE) pancreatic sections (2-4 μm thick) were processed using an automatic slide stainer Bench-markUltra (Ventana Technology, Roche Diagnostics). Deparaffinization was performed for four min at 72°C using EZPrep (Roche Ventana, #5279771001), followed by antigen-retrieval (AR) for 40 minutes at 100°C with TRIS-based CC1-buffer (Roche Ventana, #5424569001). After peroxidase-inhibition with I-View Inhibitor (Roche, #06396500001), the sections were incubated with primary

antibodies against insulin (1:1000; Dako, #A0564), glucagon (1:600; Santa Cruz, #sc13091), somato-statin (1:6000; Invitrogen, #14-9751-80), CD31 (1:100; Dako, #M0823), perilipin 1 (1:2000; Progen, #651156), and tubulin beta 3 (1:2500; R&D Systems, #MAB1195). The secondary horseradish peroxidase-linked antibody was detected via an Opti-View DAB IHC detection kit (Roche Ventana, #06396500001). The samples were counterstained with hematoxylin. WSI-acquisition was performed with a Hamamatsu NanoZoomer 2.0-HT using 20x magnification and NDP.scan 2.5 software.

Multiplex Fluorescence staining and fluorescence microscopy. Consecutive 2-4 μm FFPE sections derived from the identical pancreatic specimens as used for the chromogenic stainings underwent fluorescent labeling via an automated staining system DiscoveryUltra (Ventana Technology, Roche Diagnostics). Deparaffinization utilized EZPrep (Roche Ventana; #5279771001) for 32 min at 69°C, and subsequent AR was performed with TRIS-based CC1-buffer (Roche Ventana, #5424569001) at 91°C for 48 min. Primary antibody cocktails were applied after incubation with a human FC-receptor-blocking reagent (1:50; Miltenyi, #130-059-901).

The antibody cocktails for Stainingset 1 included for the first incubation antibodies against glucagon (1:200; Abcam plc. #Ab10988) and tubulin beta 3 (1:25; R&D Systems, MAB1195), for the second incubation mouse IgG1 con. AF555 (1:200; Invitrogen, #A-21127) and mouse IgG2a con. AF647 (1:50; Invitrogen, #A21241), and for the third incubation somatostatin con. AF750 (1:200; Novus Biologicals, #NBP2-99309 AF750) with DAPI (1 ng/ml; Invitrogen, #D1306). The cocktails for Stainingset 2 included for the first incubation antibodies against perilipin 1/PLIN1 (1:50; Progen, #690156) and PECAM1/CD31 (1:33; Abcam, #ab134168), for the second incubation mouse IgG1 con. AF555 (1:100; Invitrogen, #A21127) and rabbit IgG con. AF750 (1:50; Invitrogen, #A21039), and for the third incubation insulin con. AF488 (1:200; Invitrogen, #53-9769-82) with DAPI (1 ng/ml; Invitrogen, #D1306). WSI acquisition was performed with a slide scanner (Zeiss AxioScan.Z1 equipped with ZEN 3.1 software) at 20x magnification.

B Deep Learning Models

Model Architectures. A Multiple Instance Learning Approach (MIL) [17] is commonly used to tackle WSI classification. In MIL the individual patches are first encoded by a pre-trained feature extractor and subsequently pooled and fed together to a MIL classification algorithm that is trained to predict the image-level class label. We tested two different feature extractors on the chromogenic WSIs. The first is a Vision Transformer pre-trained on ImageNet21k [7], which consists of natural images, while the second is Phikon [8], a Vision Transformer pre-trained on over 6 thousand histologic WSIs and therefore specifically tailored to the domain. As MIL algorithm, we used Clustering-constrained Attention Multiple Instance Learning (CLAM) [6] as well as Chowder [18]. Both architectures deal with the variability in patch importance in different ways. CLAM uses an attention mechanism to focus on the most relevant patches within a bag while simultaneously imposing clustering constraints to ensure that similar patches receive comparable attention weights, enhancing interpretability and performance. We adapted the CLAM algorithm to further improve generalizability by only showing a random subset of patches of a WSI (usually 5%) to the model during an epoch. Moreover, a cosine annealing learning rate scheduler as well as gradient accumulation were added. The Chowder architecture employs a modular and hierarchical approach to MIL, where instance-level features are aggregated through a series of convolutional and pooling layers to capture complex patterns and dependencies. It also incorporates importance sampling to dynamically select the most informative instances from each bag, thereby reducing computational load and enhancing the model's ability to focus on critical data points.

Data Representations. Patches of chromogenic samples were encoded as RGB images (3 color channels) similar to natural images. In contrast, multiplex fluorescent immunostainings required further preprocessing, since in these cases each channel contains the intensity values of one of the respective stainings which does not coincide with color channels. Each of the fluorescent WSIs has 4 channels, containing 3 of the Stainingset-specific stainings as well as DAPI, as nuclear (DNA) marker. We tested 3 different data representations on the fluorescent WSIs:

- **RGB:** This representation treats each of the 3 stainings as RGB color channels and additionally overlays the DAPI channel as a grayscale image on each of the other 3 channels, resulting in an RGB image similar to what can be seen with a standard visualization software when showing all

stainings simultaneously. This representation contains the co-occurrence of the stainings, i.e. the model can learn which stainings occur together in the WSI.

- **Channel-wise:** The channel-wise representation treats each channel (staining) individually as a grayscale image. Consequently, each patch gets encoded 4 times during feature extraction. The resulting features (1-dimensional vectors) are then appended, leading to a representation where each channel is encoded in detail, but no co-occurrence information is preserved.

- **Channel-wise average:** The channel-wise average representation is very similar to the channel-wise representation but aims to include the co-occurrence of stainings by averaging the 4 different feature vectors respective to their occurrence in the image.

Training Procedure. We split the data consisting of 100 unique patients into a train (75 patients) and test (25 patients) set and performed the model development solely on the train data. For that, we used a 15-fold cross-validation, where in each fold we randomly used 60 patients from the train set for training and the remaining 15 patients for validation. Due to the different distributions of T2D within the two cohorts, we applied balanced sampling during training only for cohort 1 patients while the cohort 2 was already balanced. As the target metric, we chose the Area Under the Receiver Operating Characteristic Curve (AUROC), since for the subsequent XAI steps it is more important to have a model that has a high separability and can generally distinguish between the two classes (T2D or not) than having a model that works well with a specific cutoff as measured by the F1-Score or the Accuracy.

Representation	Stainingset	Encoder / MIL Algorithm	AUROC (higher is better)
Channel-wise Average	1	Imagenet / CLAM	**0.956**
	2	Imagenet / CLAM	0.684
Channel-wise	1	Imagenet / CLAM	**0.912**
	2	Imagenet / CLAM	0.816
RGB	1	Imagenet / CLAM	**0.842**
	2	Imagenet / CLAM	0.640

Table 2: Model performance on fluorescent WSIs.

C Attention Computation

Initially, we focused on determining the significance of specific patches using the built-in attention mechanism of the classification head. Nevertheless, raw attention data predominantly indicates general importance rather than class-specific relevance. To address the latter, we applied Attention Layer-wise Relevance Propagation (Attention LRP) [19], which filters the attention values to highlight patches distinctly associated with either diabetic or non-diabetic status within the same WSI. The class-specific relevance R is iteratively computed for each layer n. Here $x^{(n)}$ is the input at layer n with j elements and $x^{(n-1)}$ is the input of the downstream layer with i elements. w_{ji} is the respective weight matrix of the layer. Non-linear functions like GELU [20] produce both positive and negative outputs. To account for this, relevance propagation can be adjusted by forming a subset of indices q resulting in the following relevance propagation:

$$R_j^{(n)} = \sum_{\{i|(i,j)\in q\}} \frac{x_j w_{ji}}{\Sigma_{\{j'|(j',i)\in q\}} x_{j'} w_{j'i}} R_i^{(n-1)} \quad \text{with} \quad q = \{(i,j)|x_j w_{ji} \geq 0\} \tag{1}$$

We set $R^{(0)} = 1_t$ for initialization, where t is the one-hot-encoded outcome class. Based on the relevance, we compute the average relevance filtered attention $\bar{A}$ for each attention head b, with the number of heads h. To this end, we take the Hadamard product between the relevance and the attention's heads gradient $\Delta A^{(b)}$, considering only the positive relevance:

Staining	MIL Algorithm	Encoder	AUROC (higher is better)
Mean over Stainings	CLAM	Imagenet	**0.833**
	Chowder	Imagenet	0.830
	CLAM	Phikon	0.794
	Chowder	Phikon	0.781
Tubulin beta 3	CLAM	Imagenet	**0.895**
Insulin	CLAM	Imagenet	0.842
Glucagon	CLAM	Imagenet	0.842
Perilipin 1	CLAM	Imagenet	0.842
Somatostatin	CLAM	Imagenet	0.842
PECAM1	CLAM	Imagenet	0.737

$$\bar{A}^{(b)} = I + \mathbb{E}_h(\nabla A^{(b)} \odot R^{(n_b)})^+ \tag{2}$$

D   Imaging Biomarker

ROI Segmentation. To compute the identified biomarkers a segmentation map of the respective regions is needed. Due to the amount and size of the WSIs we used scribble annotation [21] to efficiently label 44 (out of 600 chromogenic WSIs) slides with the labels background, tissue, adipocytes, fibrotic patterns, and islets. Scribble annotation allows for a very fast annotation because regions are not annotated densely (i.e. each pixel gets annotated) but rather only smaller lines (scribbles) are used to approximately label the respective regions. During model training, we used the ignore label in nnU-Net [22] to only update the model weights based on annotated scribbles

while ignoring the remaining image. While annotation is based on scribbles, the model still returns a dense prediction which makes this approach well-suited for segmenting the ROIs. Since the nature of scribbles only allows a quantitative evaluation of the respective annotated areas, a qualitative analysis of the resulting segmentation maps was conducted. After adjusting some annotations and retraining the nnU-Net, a satisfactory segmentation quality was reached.

Quantifying Attention.　The attention to specific ROIs for the chromogenic stainings was computed by summing up the raw attention within specific segmentation masks and standardizing it by the total attention in the WSI and the tissue size. We summed up the attention per staining channel for the fluorescence stainings and standardized it by the total attention over all stainings and the tissue size. For the exploratory analysis, we z-standardized all continuous variables on non-interpretable scales; however, we routinely z-standardized all continuous covariates for the statistical analysis.

Biomarker.　For the chromogenic staining, we computed the area-related biomarkers based on the segmentation masks and counted the number of distinct islets and adipocyte clusters by applying connected components to the respective segmentation mask. All biomarkers are standardized by the total size of the tissue. For the islet-related biomarker, we only include islet segmentations larger than 5000 pixels, ignoring segmentation artifacts or errors. For the fluorescence-specific intensity biomarkers, we computed the channel-specific mean intensity as an approximation of the respective area of the trait and standardized it again by the tissue size. In the case of perilipin 1, we first threshold the intensity values, including only values larger than 1000 (intensity measured as 16-bit integers), filtering out unspecific stained traits. For tubulin beta 3 within islets, we only included the intensity within islets and additionally, standardized by the number of islets.

E   Statistical Methods

Hypothesis Testing.　To test differences between two groups, e.g. patients with and without diabetes, we applied a two-sample t-test. For testing, if at least one group is significantly different, we applied the F-test within a one-way ANOVA. To test if a coefficient in a linear model is significantly different from zero we used the Z-test. For all tests, we considered p-value > 0.05 as not significant.

Statistical Models.　For statistical analysis of the biomarkers, we used a generalized mixed linear model (GMLM), as we have several dependence structures within the data. For the diabetes status as the outcome, we selected the canonical binomial link function. For the HOMA2B level, we selected the canonical Gaussian and Gamma link functions and reported results for the Gaussian link, as its Akaike Information Criterion (AIC) was lower. We accounted for random effects linked to the cohort and staining method. Due to no variation between the outcomes (i.e., diabetes status) within a patient, we could not model the patient as a random effect. In this case, the intercept would be enough to fit one model per patient perfectly. All models were fitted via maximum likelihood and the L-BFGS-B optimizer [23]. We tested for multicollinearity by computing variance inflation factor (VIF) and removed "benign tumor" due to perfect multicollinearity with "malignant tumor" combined with "chronic pancreatitis". Sensitivity analyses were performed using generalized estimating equation (GEE) models.
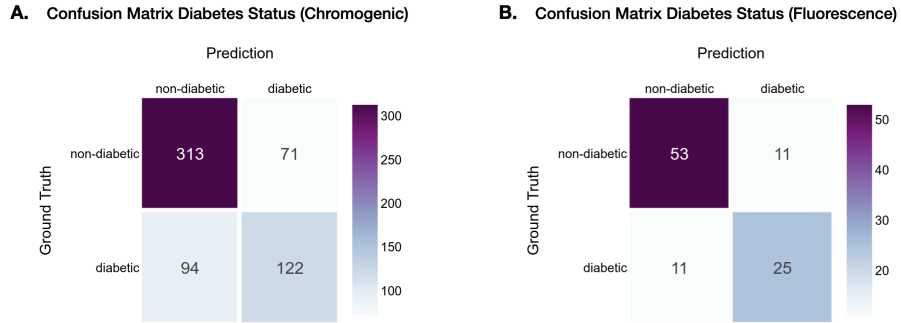

A. Confusion Matrix Diabetes Status (Chromogenic)

B. Confusion Matrix Diabetes Status (Fluorescence)

Figure 6: Top 15 attended chromogenic patches.

Statistical Model Evaluation. For all models with the same modality and response variable, we used the AIC for model selection. Additionally, we evaluated the logistic models through a confusion matrix (Figure 6) and the linear models through parity plots, residual plots, and Q–Q plots of the residuals (Figure 7).

F   Limitations

While this data-driven approach has the potential to accelerate and facilitate the understanding of T2D pathogenesis, several potential limitations must be considered. One is that immunostaining approaches can be associated with technical pitfalls such as antibody binding specificity, nonspecific background staining, or variations in the staining intensity across samples regardless of target antigen level. Furthermore, our histological preparations were not representative of the whole organ, since

they were obtained from limited regions of the pancreas, the anatomical location of which varied among living donors. Further, despite originating from the "healthy" margins of the surgical resection, as also verified by postoperative pathological assessment, the samples could be affected by changes in the tissue microenvironment such as inflammation, enrichment of connective tissuefocal fibrosis, and angiopathy.
