FIRST: FINETUNING ROUTER-SELECTIVE TRANS FORMERS FOR INPUT-ADAPTIVE LATENCY REDUC TION

Anonymous authors

Paper under double-blind review

ABSTRACT

Auto-regressive Large Language Models (LLMs) demonstrate remarkable performance across domanins such as vision and language processing. However, due to sequential processing through a stack of transformer layers, autoregressive decoding faces significant computation/latency challenges, particularly in resourceconstrained environments like mobile and edge devices. Existing approaches in literature that aim to improve latency via skipping layers have two distinct flavors - 1) Early exit 2) Input-agnostic heuristics where tokens exit at pre-determined layers irrespective of input sequence. Both the above strategies have limitations - the former cannot be applied to handle KV Caching necessary for speed-ups in modern framework and the latter does not capture the variation in layer importance across tasks or more generally, across input sequences. To address both limitations, we propose FIRST, an algorithm that reduces inference latency by using layer-specific routers to select a subset of transformer layers adaptively for each input sequence - the prompt (during prefill stage) decides which layers will be skipped during decoding. FIRST preserves compatibility with KV caching enabling faster inference while being quality-aware. FIRST is model-agnostic and can be easily enabled on any pre-trained LLM. We further improve performance by incorporating LoRA adapters for fine-tuning on external datasets, enhancing task-specific accuracy while maintaining latency benefits. Our approach reveals that input adaptivity is critical - indeed, different task-specific middle layers play a crucial role in evolving hidden representations depending on task. Extensive experiments show that FIRST significantly reduces latency while retaining competitive performance (as compared to baselines), making our approach an efficient solution for LLM deployment in low-resource environments.

1 INTRODUCTION

Large Language Models (LLM's) have revolutionized the fields of Natural Language Processing and Computer Vision achieving incredible performance on a diverse set of benchmark tasks. However, 040 the scale of these LLM's characterized by billions of parameters hinder their adoption in resource-041 constrained environments with memory, latency and compute serving as the main challenges. In this 042 work, we focus on the latency aspect which becomes the most significant bottleneck for tasks such as 043 machine translation, question answering, summarization particularly on devices, such as laptops and 044 mobile phones. As mentioned in (Schuster et al., 2022), the auto-regressive nature of decoding in 045 LLM's further pronounces the latency bottleneck. Our main interest lies in the resource-constrained on-device setting where resolving this bottleneck is of particular importance. 046

Transformer based LLMs have several stacks of layers (including attention and FFN layers) leading
to high latency and compute requirements, making inference very slow or even infeasible in resource
constrained settings. This is because of the sequential processing of tokens through all the layers
for *every input sequence and task*. However, it is important to note that in the real world, there is
a lot of heterogeneity in input sequences and tasks. (Schuster et al., 2022; Sun et al., 2022) noted
that the generations made by LLMs can have varying levels of difficulty and certain generations can
be solved with reduced compute, by exiting the transformer stack early. At the same time, it has
been noted in recent works (Wendler et al., 2024) that inference forward pass proceeds in phases

through the layers of transformer based models, with different types of information being extracted 055 or mapped at different phases (sequences of layers) for certain tasks such as translation. Motivated 056 by these and other related works, we hypothesize that *different sequential combinations of layers* 057 are important for different input sequences and tasks. Learning the right sequential combination 058 of layers can help reduce inference latency and compute for on-device scenarios. However, there are several challenges. Any algorithm for determining the "right" combination of layers should minimize any quality loss, be compatible with other latency reduction strategies such as KV cache 060 handling and batch inference, should not introduce any additional latency or compute and and be 061 learnable with minimal compute and training overhead. 062

063 In the last few years, several promising approaches have been proposed in literature that adaptively 064 prune layers at each decoding step. Token-level early exit proposed in (Schuster et al., 2022; Sun et al., 2022) allow tokens to exit the transformer layer stack early based on different strategies to 065 compute the confidence or saturation level. (Elhoushi et al., 2024; Elbayad et al., 2020; Zhang et al., 066 2019) extended this idea to incorporate layer skipping at a token level during training. While token 067 level early exit is a useful idea in theory, it suffers from a major limitation of incompatible KV 068 Caching in practice (Del Corro et al., 2023). The incompatibility stems from having to recompute 069 KV caches for preceding tokens if we have a delayed exit point for latter tokens often resulting in loss of early exit advantages. Since KV cache is crucial in significantly speeding up auto-regressive 071 decoding, inappropriate handling of KV cache limits practical adoption. 072

Recently, (Liu et al., 2024; Del Corro et al., 2023) have proposed input-agnostic layer skipping at 073 token level, that handle KV cache appropriately as well as retain the advantage of adaptive partial 074 computation. In these solutions, tokens exit at pre-determined layers irrespective of the input se-075 quence, and for all sequences in a batch, tokens at the same position in a sequence exit at the same 076 layer. Furthermore, tokens at latter parts of the sequence are constrained to exit earlier than the 077 previous tokens to ensure that there is no redundant KV cache re-computation. These solutions are heuristic based and impose hard rules and constraints irrespective of input sequences, which can 079 lead to drop in output quality. Others (Jaiswal et al., 2024) have proposed circumventing the KV cache issue entirely by skipping only FFN layers, but such a strategy cannot reduce redundancy in 081 transformer layer computations. Moreover, they propose an input adaptive skipping heuristic based on cosine similarity of outputs: if two adjacent layers have a similarity greater than a threshold, then all subsequent layers except the last few are skipped. However, such a strategy does not take into ac-083 count that several middle layers are crucial (see (Liu et al., 2024)) and furthermore, final prediction 084 capability of full model is not taken into account while deciding which layers to skip. 085

Our goal is to design an input-adaptive learnable layer selection strategy with quality aware latency 087 gains that is also able to handle the KV Cache appropriately. Ideally, for every input sequence 880 and task, we want to predict the optimal (sequential) combination of layers at inference time, such that quality loss is minimum and the latency gains are as high as possible. We want to do this 089 with expending very little compute/additional training, with no or minimal additional latency (for 090 inference) and handle KV cache appropriately. Since there are exponential number of possible 091 layer sequences, this seems like a hard goal computationally and otherwise - however, we have 092 addressed this layer selection challenge partially in this work. We propose an approach for learning 093 and predicting the layer selections based on the input sequence and task, via training routers. Based 094 on the output of each layer for a sequence, a router will decide whether or not to skip the subsequent 095 layer in the transformer architecture. Since the decision is at a sequence level, KV cache issues 096 do not arise, as all tokens in a sequence would pass through the same set of layers. Moreover, we 097 further generalize our approach to handle batch inference by making the layer selection unified for 098 all sequences in a batch. Finally, we fine-tune the model combined with trained routers using LoRA adapters to improve the quality significantly while retaining the latency gains. As an added bonus, 099 LoRA finetuning smoothens the layer skipping ¹, reduces the amount of performance degradation 100 and further highlights the varied importance of layers based on input sequence. 101

102 We summarize our contributions below:

- 1. We propose a training and inference algorithm FIRST that incorporates layer-specific routers for selecting layers in an input-adaptive manner. The layer selection is uniform for all tokens in a
- 105 106 107

103

¹Depending on the task, after LoRA finetuning, task-specific sequences skip a certain set of middle layers significantly more than other middle layers

sequence, thus handling KV caching and batch decoding without introducing additional compute
 and latency. This can be applied on top of any pre-trained model.

- 2. We further incorporate LoRA adapters on top of the router-based layer selection for finetuning on external dataset the goal is to improve the quality of performance of the router-augmented model on the task-specific data while retaining latency gains. This further smoothens the layer selection and an important insight emerges: certain layers including several middle layers (sequence-dependent) are significantly more important for evolving the hidden representation.
- 3. Finally, we demonstrate extensive experimental evidence on multiple datasets on Machine Translation and Summarization tasks answering the efficacy of FIRST in achieving good latency gains while retaining comparable quality of performance.

120

2 RELATED WORK

121 Early Exit: Several works have been proposed in the early exit theme (Zhu, 2021; Zhou et al., 122 2020; Xin et al., 2020; Liu et al., 2020; Li et al., 2020; Hou et al., 2020; Schuster et al., 2022) 123 where adaptive compute is used for different parts of the token sequence. While these approaches have been popular for encoder-only models which processes the entire sequence as a whole, they 124 have faced challenges in generation tasks. The main limitation of these set of techniques are their 125 inability to handle KV caching appropriately which is crucial for multi-fold speed-ups in current 126 LLM architectures. We emphasize that in our work, we assign varying compute to sequences in 127 different batches but within the same sequence, we assign the same compute to every token. 128

129 Input Agnostic Heuristics: In Skip Decoding (Del Corro et al., 2023), initial tokens pass through 130 more layers than later ones, contradicting the observation that later tokens are harder to decode (Liu et al., 2024). Additionally, Skip Decoding skips several bottom layers for most tokens, causing 131 undesirable sub-network imbalance. To address this, Unified Layer Skipping (Liu et al., 2024) pro-132 poses a discrete skipping strategy that is uniform for all tokens in a sequence. Based on a latency 133 budget, retained layer ids are passed through by all tokens, ensuring KV Cache handling and retain-134 ing key layers. However, the limitation of this approach is that skipping is independent of the input 135 sequence. In contrast, early exit strategies adapt layer skipping to the input sequence, offering more 136 flexibility. In (Fan et al., 2019), a method akin to dropout randomly skips layers during training, 137 but this leads to performance decline during the pre-fill stage. FFN-SkipLLM (Jaiswal et al., 2024) 138 constrains skipping to FFN layers to avoid KV Cache issues but fails to fully exploit redundancy as 139 discussed already.

140 Model Compression and Quantization Aware Training: Orthogonal approaches to explore the 141 latency/memory-performance trade-off in Large Language Models aim to build smaller models that 142 approximate the performance of larger ones with reduced memory and latency costs. Key techniques 143 include: 1) compressing model parameters into fewer bits (Frantar et al., 2022; Lin et al., 2024; Lee 144 et al., 2024; Saha et al., 2023); 2) pruning the network by removing components like attention heads 145 or neurons based on heuristics (Frantar & Alistarh, 2023; Ma et al., 2023); and 3) distilling the large 146 model into a smaller, faster counterpart (Agarwal et al., 2023; Gu et al., 2024). For further details, we refer to the survey by (Zhu et al., 2023). A significant body of work (Dettmers et al., 2024; Liu 147 et al., 2023b; Peri et al., 2020; Li et al., 2023) has focused on quantization-aware training to reduce 148 memory footprints and mitigate performance loss, starting with QLoRA (Dettmers et al., 2024). In a 149 similar vein, our work proposes fine-tuning router-augmented models to improve layer skipping and 150 reduce performance degradation, as pre-trained models do not account for layer skipping, leading to 151 higher degradation with vanilla skipping. 152

153

3 PROBLEM STATEMENT

154 155

Our goal is to exploit the heterogeneity in inputs and tasks to selectively use LLM layers in a quality aware manner for reducing inference latency and compute for on-device constraints. Ideally, we want to select an *optimal* sub-sequence of layers within a transformer architecture for a given input and task, such that the overall latency as well as expended computation are both low, while quality is comparable to the un-modified case where every input sequence passes through every layer. For ease of explanation, without loss of generality, we assume the task is same and simply consider an input sequence for describing the problem. 162 Let us consider an an input sequence $\mathcal{X} = \{x_1, x_2, \dots, x_n\}$ with *n* tokens. Let there be *m* transformer layers in the model, where the i^{th} transformer layer is represented as the function $\phi_i()$. 163 As stated lucidly in (Wendler et al., 2024), \mathcal{X} is first converted to an initial latent representation $\mathcal{H}_0 = \{H_0^1, H_0^2, \dots, H_0^n\}$, where $H_j^0 \in \mathbb{R}^D, \forall j \in [n]$ is a look-up from a learned embedding 164 165 dictionary corresponding to the j^{th} token. Thereafter, every transformer layer $\phi_i()$ operates on the 166 latent vectors \mathcal{H}_i to generate the embedding for the i^{th} layer as follows. For the j^{th} token, 167 168

$$H_i^j = H_{i-1}^j + \phi_i(H_{i-1}^1, H_{i-1}^2, \dots, H_{i-1}^j)$$
(1)

Let the (golden) output or generated sequence for an input sequence \mathcal{X} that passed through all m 171 layers of the model with full computation be $\mathcal{Y}_{\mathcal{Y}}^*$. Our hypothesis is that for a given input sequence 172 (and task), there exists an optimal subsequence of functions $\mathcal{F}_{OPT}(\mathcal{X})$ out of the full sequence 173 $\{\phi_i, i \in [m]\}\$ such that the output generated by passing through this subsequence: $\mathcal{Y}_{OPT,\mathcal{X}} \approx \mathcal{Y}_{\mathcal{X}}^*$. 174 More formally, if Q is a quantitative quality measure on \mathcal{Y} , and $\epsilon \to 0$ is tolerance in deviation in 175 quality from the golden output, then we hypothesize that there exists an optimal subsequence, using 176 the minimum number of layers, $\mathcal{F}_{OPT}(\mathcal{X})$, such that: 177

$$Q\left(\mathcal{Y}_{OPT,\mathcal{X}}\right) \ge (1-\epsilon)Q\left(\mathcal{Y}_{\mathcal{X}}^{*}\right), \forall \mathcal{X}.$$
(2)

179 The optimality above is with respect to the minimum subsequence of layers that can help achieve the above, to minimize latency while keeping quality unaffected. Note that, the optimal subsequence 181 $\mathcal{F}_{OPT}(\mathcal{X})$ need to be obey the same autoregressive computation on previous tokens as given in 182 Equation 1. Hence, any algorithm that determines the optimal subsequence, need to be compatible 183 with KV cache handling, to avoid the re-computation of values for tokens preceding the current 184 token (which is a drawback with some existing work, especially in the Early Exit literature, that 185 choose computation or layer skipping at token level).

186 The potential number of subsequences for m layers is 2^m , hence a brute force approach is not only 187 infeasible, but would also beat the purpose of such a layer selection in the first place: reducing 188 latency and compute. In the absence of any known substructure in the behaviour of the latent layers 189 on each input sequence, it is difficult to arrive at such an optimal solution polynomially or with low 190 additional latency or compute, and in fact is likely to be NP-hard. 191

We propose to learn an approximation of the optimal subsequence of layers for any input sequence 192 with low additional latency and minimal training. 193

194 195

196

169 170

178

PROPOSED SOLUTION: FIRST 4

Let us first understand what it entails to learn an optimal subsequence of layers for any input. Con-197 sider the full transformer sequence to be $F^* = \{\phi_1, \phi_2, \dots, \phi_m\}$. Any optimal subsequence for an input \mathcal{X} : $F_{OPT,\mathcal{X}}$ could be thought of as finding an optimal path through a binary tree of func-199 tions. Formally, let every level in the binary tree correspond to a transformer layer and the 0^{th} layer 200 corresponds to the initial embedding look up; i.e., at depth $i \in [m]$, there would be 2^i nodes, each 201 corresponding to either ϕ_i or $\overline{\phi_i}$, where the former denotes that a particular transformer layer is in-202 cluded in the optimal path whereas the latter denotes that it is not included. Each (of the 2^{i-1} nodes) 203 ϕ_i or $\overline{\phi_i}$ has two children, corresponding to the next transformer layer: ϕ_{i+1} and $\overline{\phi_{i+1}}$ (See Figure 1). 204 In such a tree structure, for example, the path $\{\phi_{i-1}, \overline{\phi_i}, \phi_{i+1}, \phi_{i+2}\}$ indicates the subsequence of 205 transformer layers $\{\phi_i, \phi_{i+2}\}$. For any transformer layer ϕ_i in this tree, let $Anc(\phi_i) = k, 0 < k < i$ 206 denote the lowest ancestor node where the corresponding transformer node ϕ_k is included in the 207 sequence. In the above example, $Anc(\phi_{i+2}) = \phi_{i-1}$. 208

For any such sequence of functions \mathcal{F} , at level *i*, the autoregressive computations for the *j*th position 209 corresponding to the j^{th} token in the input sequence, Equation 1, would now be modified as follows. 210

$$H_{i}^{j} = \begin{cases} H_{k}^{j} & \text{if } \phi_{i} \notin \mathcal{F}, \ k = Anc(\phi_{i}) \\ H_{i}^{j} & \text{if } \phi_{i} \notin \mathcal{F}, \ k = Anc(\phi_{i}) \end{cases}$$

$$= \begin{cases} H_k^j & \text{if } \phi_i \notin \mathcal{F}, \ k = Anc(\phi_i) \\ H_k^j + \phi_i(H_k^1, H_k^2, \dots, H_k^j), & \text{if } \phi_i \in \mathcal{F}, \ k = Anc(\phi_i) \end{cases}$$

(3)

212 213 214

211

Our problem translates to navigating this binary tree to find the optimal path \mathcal{F}_{OPT} for any given 215 input sequence and task. Since there are 2^m paths in this tree, we propose to approximate the

Figure 1: Binary Tree representation of the subsequence of layer selection.

optimal choice by making this decision in a greedy fashion at each node. Formally, we propose to add a (lightweight and fast) router R_i before every transformer layer ϕ_i in the model, that will predict whether ϕ_i will be selected or not.

Our aim is to learn to predict the layer choice at each level (myopically) so that the overall path (or, sequence of functions) $\mathcal{F}(\mathcal{X}) \approx \mathcal{F}_{OPT}(\mathcal{X})$ for any given input sequence \mathcal{X} (and task). We want to decide this at a sequence level, and not at a token level to maintain compatibility with the autoregressive computations and avoid re-computation of values (use KV cache efficiently). Moreover, we want to spend minimal compute and training for learning these functions R_i and finally, R_i functions should be lightweight and low compute so that that do not add any significant latency to the overall computation, helping realize the latency gains.

Our proposed algorithm FIRST modifies any off-shelf pre-trained transformer based model by incorporating and training a router or probability function R_i before every transformer layer ϕ_i . For a given input sequence \mathcal{X} , the output of the router R_i is a probability score ρ_i denoting the probability of selecting ϕ_i in the layer sequece. We can think of layer *i* as a modified function $\phi_i^R((X))$ such that the output is $\rho_i \cdot \phi_i(\mathcal{X}) + (1 - \rho_i) \cdot \phi_i(\mathcal{X})$. Formally, the autoregressive computation in Equation 1 would now be modified as follows.

253

254 255

216

217

218

219

220

221 222

228 229 230

$$H_{i}^{j} = H_{i-1}^{j} + \rho_{i} \cdot \phi_{i}(H_{k}^{1}, H_{k}^{2}, \dots, H_{k}^{j}) + (1 - \rho_{i}) \cdot \phi_{i}((H_{k}^{1}, H_{k}^{2}, \dots, H_{k}^{j}))$$
(4)

The above equation, applied recursively would be approximating the Equation 3 for the optimal \mathcal{F} in a probabilistic, greedy manner. We train the functions ρ_i on datasets and task, and further fine tune using LoRA adapters to make the layer selections smooth and improve the output quality. We explain the framework for FIRST algorithm in details in the following section.

5 FIRST FRAMEWORK AND ALGORITHM

In this section we describe the training and inference frameworks and procedure for FIRST in de-256 tails. We first describe how to train Routers to be adaptive to input sequences. Given an off-the-shelf 257 pre-trained LLM, we propose two training phases (Figure: 2). In the first phase, we train a router 258 for each layer that decides whether the tokens in the input sequence should skip the layer or not. In 259 the second phase, to tackle the issue of unseen skipping during pre-training, we fine-tune the router-260 augmented LLM keeping router weights fixed using LoRA (low rank adapters) to ensure the model 261 learns to perform well on the target dataset without reducing the skipping level. In other words, 262 the LoRA fine-tuning ensures that the gap in performance with and without skipping is significantly 263 reduced when compared to the base model. Below, we provide the details of each phase.

264 265 266

5.1 Adaptive Router Module

The adaptive router module is a single-layer neural network without bias, positioned before every layer in the model. During training of the router, all model parameters except the router weights remain frozen. For the first layer, it takes the tokenized input, and for each of the subsequent layers, it takes the output of the preceding layer as input. Mathematically speaking, for any layer *i*, given

Figure 2: Layer diagram of the two training phases

a batch of *B* tokenized inputs sequences, where each sequence has *n* tokens and is embedded in to \mathbb{R}^D , the adaptive router module takes as input a $B \times n \times D$ tensor output of layer (i - 1) and outputs a $B \times n \times 1$ tensor. Subsequently, corresponding to each value (or, token) in the $B \times n \times 1$ tensor, we apply a sigmoid function to ensure that all entries in the tensor are in the interval [0, 1]. Following this, we take a mean operation at the sequence level - we take a mean of all the weights in a sequence to output a $B \times 1 \times 1$ tensor. For each sequence in the batch, the corresponding entry is the probability ρ_i with which the sequence passes through the layer *i*. The input sequence skips the layer *i* with probability $1 - \rho_i$.

In summary, after applying router R_i to an input sequence at each layer *i*, a single probability value p_i is produced, indicating whether to pass the sequence through the layer. During training, the output of a layer is modified as in Equation 4 using a skip connection, incorporating the probability ρ_i (see Figure: 3). The routers are trained to encourage skipping by reducing the probabilities ρ using a regularizer, to approximate the optimal subsequence for minimizing the latency. Note that the entire model is frozen except for the routers. The training task is modeled as a language modeling task, specifically next token prediction. The total loss function comprises of 3 terms namely -

- Cross-entropy loss: This measures the difference between the actual and predicted probability distributions, to ensure the quality of the generations. $\mathcal{L}_{CE} = -\sum_{x \in \mathcal{X}} \mathcal{Y}_{\mathcal{X}}^* \log(\hat{\mathcal{Y}}).$
- **Regularization loss:** This adds a penalty term to the loss function so that the router parameters are not too large, to minimize the added latency and training compute, as well as minimizing overfitting to noise. $\mathcal{L}_{\text{Reg}} = \sum_{i \in [m]} ||R_i||^2$, where $||R_i||^2$ denotes the ℓ_2 norm of the router weights for the *i*th layer router, and there are *m* layers in the model.
 - Non-skip Penalization loss: Summation of probability values across all layers of the model architecture. It encourages the model to favor skipping at the cost of cross-entropy loss to reduce latency, with the coefficient α , managing the extent of skipping to approximate the optimal tradeoff of quality and latency. $\mathcal{L}_{PP} = \sum_{i \in [m]} \rho_i$.
- The total loss is a linear combination of these three terms namely $\mathcal{L} = \mathcal{L}_{CE} + \lambda \cdot \mathcal{L}_{Reg} + \alpha \cdot \mathcal{L}_{PP}$.

313 314 5.2 LORA COMPENSATION MODULE

315 Selecting a subsequence of layers in a model to improve the latency during inference will naturally 316 come with some performance loss - especially so since the pre-trained model was not trained to skip 317 layers given any input sequence. To compensate for the loss in performance caused by skipping in 318 the model, we finetune the router-augmented pre-trained model on the downstream task. We are 319 inspired by Quantization Aware Training - QLoRA in particular - a training method which com-320 pensates for performance loss due to model compression. To finetune, we use Low Rank Adapters 321 (LoRA) to modify the weights of the pre-trained model while keeping the router weights frozen. While using LoRA, the difference in weights for each trainable weight matrix is restricted to be a 322 low rank matrix. During training, the router parameters are frozen while trainable LoRA adapters 323 are added to both the FFN (Feed-Forward Network) and the attention modules of each layer of the

Figure 3: Skip connection used for router training. With probability p, the sequence is processed by the layer and with probability 1 - p, the layer is skipped. During inference, routers make the decision of whether a sequence will skip a particular layer or pass through it.

340 pre-trained model. During the finetuning phase, to maintain the skipping level, we again add a similar loss component as in phase 1, namely $(\alpha/3)\mathcal{L}_{PP} = (\alpha/3)\sum_{i\in[m]}\rho_i$. This is essential during 341 342 the LoRA finetuning even though the router weights are fixed in this phase - this is because the 343 finetuning mechanism alters the hidden representations of the input sequence in a manner such that the probability score for each layer is always more than 0.5 implying that no layers are skipped. 344 We have noticed that the Non-skip Penalization Loss coefficient α scaled down by a factor of 3-4 345 is well-suited for the finetuning process while maintaining the same skipping level as in phase 1 of 346 the training. During training the LoRA adapters, responses are appended to the prompt to train the 347 model to predict tokens from the response. For inference, the model weights are merged with the 348 original weights to prevent any latency overhead. 349

350 5.3 INFERENCE FOR FIRST351

During inference, given an input sequence, the decision to skip or pass through a layer is determined by a threshold. For the input sequence, each router (corresponding to a layer) outputs a number in the interval [0, 1]. If this number (corresponding to the probability of not skipping the layer) is greater than or equal to 0.5, the sequence passes through the layer. On the other hand, if the output from the router is less than 0.5, the sequence skips the layer (Figure: 3). Below, we describe some salient points about the functioning of the router during inference to handle KV Cache appropriately to retain the modern latency speed-ups:

- Prefill phase handling: Skipping is not allowed during prefill phase. This ensures the first token is generated correctly, which is crucial for WMT tasks, as they are highly sensitive to the correct generation of the first token in the target language. It has been observed in prior works (Liu et al., 2024) that skipping during prefill phase is detrimental to performance during inference.
- 2. Fixed router decisions during decoding and handling KV Cache: During the prefill phase, the decisions made by the routers are cached. During the decoding phase, every token adheres 364 to the cached decision made during prefill. In other words, for a particular layer, if a router 365 outputs a number less than 0.5 during prefill, the number is fixed for the decoding steps and 366 therefore the same layer will be skipped by all tokens during decoding. Similarly, if the router 367 outputs a number more than 0.5 during prefill, the same layer will be processing all tokens during 368 decoding. Such a step ensures that for each decoding step and each layer that is not skipped, 369 the KV cache for all previous tokens is available for that layer - this is because a fixed set of 370 layers (decided during the prefill phase) will be skipped for all tokens during the decoding phase 371 of inference. This approach effectively addresses the caching issues encountered in early exit 372 strategies, ensuring consistent decisions across the decoding process.

375 376

377 We conduct experiments on two benchmark tasks: Machine Translation and Text Summarization on several publicly available datasets demonstrating both robustness and scalability of FIRST.

378 6.1 DATASETS

Machine Translation: For translation tasks, namely English-to-Chinese and English-to-German,
 we employ the WMT development sets from 2017 to 2020 for training/fine-tuning following the
 methodology outlined in previous studies (Liu et al., 2023a; Jiao et al., 2023). Translation performance is evaluated using the test set from the WMT 2022 dataset (Kocmi et al., 2022) which was
 developed using recent content from diverse domains. These domains include news, social media,
 e-commerce, and conversational contexts. (Details in Appendix: A.1, Table: 4).

386 Summarization: We use the popular CNN-DailyMail (CNN-DM) (Hermann et al., 2015) dataset 387 which is a large collection (over 300k) of text summarization pairs, created from CNN and Daily 388 Mail news articles. Each datapoint in this dataset comprises of an article (the body of the news article with 683 words on average) and the corresponding highlights (article summary as written by the 389 article author). While the training set contains more than 287k samples, we have randomly chosen 390 4k samples for training both routers and LoRA. During training in our framework, the number of 391 trainable parameters is small in both phases - therefore a small subset of data points is sufficient for 392 training. Inference is performed on the standard test set with 11,490 samples. 393

395 6.2 EVALUATION METRICS

Quality-Based Metrics for Translation task:

- **BLEU Score:** BLEU (Bilingual Evaluation Understudy) scores are used to measure the quality of translations. BLEU compares n-grams of the candidate translation to n-grams of the reference translation, providing a score between 0 and 1, with higher scores indicating better translations. In this evaluation, NLTK BLEU is employed, focusing on BLEU-1 and BLEU-2 scores.
- **COMET:** COMET (Cross-lingual Optimized Metric for Evaluation of Translation) is used to assess translation quality further. COMET evaluates translations using a model trained to correlate well with human judgments. Specifically, Unbabel/XCOMET-XL² is used in this evaluation. COMET provides a more nuanced assessment of translation quality by considering the intricacies of both source and target languages, beyond the n-gram matching used in BLEU.

Quality based Metrics for Summarization Task:

- **BERTScore:** This metric quantifies semantic similarity between texts by leveraging contextual word embeddings. BERTScore captures meaning-based similarity rather than relying on exact word matches, providing a nuanced evaluation of text generation quality.
- **ROUGE:** (Recall-Oriented Understudy for Gisting Evaluation) is a common metric ROUGE-1 refers to overlap of unigrams between the system summary and reference summary. Similarly, ROUGE-L measures longest matching sequence of words.

Finally, for benchmarking latency, we look at the **TPOT** (**Time Per Output Token**): This metric
evaluates the average time taken to produce each output token and is calculated for GPU to gauge
overall decoding performance.

6.3 TRAINING AND INFERENCE SETUP

419 • Training settings: For our experiments, we use Llama-3-8B base model from Meta, which com-420 prises of 32 layers. Training of routers and LoRA adapters is conducted on A100 80GB GPUs, 421 with training/inference is performed in full precision to avoid performance degradation due to 422 quantization. The training process employs our custom loss function and continues for a fixed 423 number of epochs, terminating when the validation loss fails to improve over 4 consecutive steps. 424 The learning rate is set between $1e^{-4}$ and $3e^{-4}$ - a cosine scheduler is used to adjust the learning rate. Gradients are accumulated after 5 steps and the regularization coefficient λ is fixed at 426 0.01. For LoRA fine-tuning, we employ a rank of 8, a dropout rate of 0.1, and a scaling factor 427 (lora_alpha) of 32. For translation, the maximum sequence length is set to 128 for router training and 256 for LoRA training. Similarly, for summarization, the maximum sequence length is set to 428 500 and 700 respectively. Prompts for the different tasks regarding training/inference are shown 429 in Appendix A.2. 430

⁴³¹

²https://github.com/Unbabel/COMET

Inference settings: For both translation and summarization, we set the temperature to 0.8 and enable top-k sampling over 10 tokens. The maximum number of tokens to be generated is set to 80 and 200 respectively. Caching is turned on during inference.

472

473

• Original Model: We compare the performance of the base model (Llama-3-8B) with and without LoRA fine-tuning as our baseline. We then train routers and the LoRA module for various values of the coefficient α associated with the non-skip penalization loss. This allows us to report the time per output token (TPOT) and quality at different levels of skipping, with and without LoRA. Latency speedups are reported relative to the LoRA-fine-tuned model, which natively supports key-value (KV) caching.

• Unified Skipping: This method relies on using a heuristic-based strategy for retaining layers at fixed intervals. We replicate their algorithm (Liu et al., 2024)and compare performance both with and without LoRA fine-tuning across various skipping percentages. We do not consider other input-agnostic heuristic-based strategy for skipping layers since Unified Skipping has empirically established itself to be the state-of-the-art.

449 6.5 DETAILED RESULTS

450 **Laver-wise Skipping Patterns:** First, we present some layer-wise skipping statistics across the 3 451 tasks that we experiment with. Note that layer-wise skipping significantly vary across tasks, indi-452 cating that the importance of each layer depends on the nature of the task and dataset. For a 15% 453 skipping rate, we observe the following patterns. In the WMT Machine Translation task, for English-454 to-German translation, layers 7–9 and 21 are fully skipped, while layer 18 is partially skipped. For 455 English-to-Chinese translation, layers 7–9, 16, and 21 are fully skipped, with partial skipping in 456 layer 20. In the summarization task, layers 20, 22, and 23 are fully skipped, and layers 19, 21, and 457 26 are partially skipped. Some layers are skipped less than 5% of the time, suggesting these layers are only necessary for specific sequences, highlighting the input-dependent and task-specific nature 458 of layer importance. Detailed layer-wise skipping statistics can be found in Appendix A.3. 459

Now, we present detailed analysis of our experiments on the WMT Translation and CNN Summa rization datasets. We start with highlighting the salient points:

462 463 English-to-German:

- 464
 1. We observe a performance degradation of less than 15% in COMET scores which accounts for the semantics part of the translated text. Less than 10% and 20% degradations are observed in BLEU-1 and BLEU-2 (syntax-based metrics) respectively for approximately 15% skipping (Table: 1). The corresponding latency improvement is 10% on TPOT. (Table: 2).
 - 2. Our approach significantly outperforms the input-agnostic layer skipping method (Liu et al., 2024), referred to as Unified Skipping. For approximately 15% skipping, our method achieves a BLEU-1 score of 38.01, compared to 28.92 for the unified skipping approach (Table: 1). In terms of COMET scores, our method attains a score of 82.14, while unified skipping achieves a score of 59.34. This demonstrates the superiority of our approach in preserving semantic integrity.

English-to-Chinese:

- 474
 1. For approximately 15% skipping, we observe a 12% improvement in TPOT (Table: 2), accompanied by a performance degradation of less than 20% in COMET scores. Concurrently, we observe close to 15% and 25% degradation in BLEU-1 and BLEU-2 respectively (see Table: 1).
- 477
 2. Our results for English-to-Chinese translation demonstrate competitive performance compared to the Unified Skipping baseline at 15% skipping, the evaluation metrics on BLEU-1, BLEU-2 and COMET scores for our FiRST framework are equivalent to the Unified Skipping baseline.

For more detailed results of the machine translation task, comprising of all four BLEU scores
 (BLEU-1, BLEU-2, BLEU-3, BLEU-4), please refer to the Appendix A.4.

482 483 CNN/DailyMail Dataset:

 There is an improvement in ROUGE-1, ROUGE-L scores (Table: 3) over LoRA fine-tuned base model suggesting that strategically skipping certain layers may even led to improved model performance. A 12% improvement in TPOT is observed for roughly 15% skipping. (Table: 2) 2. Our method outperforms Unified Skipping approach with more than 30% improvement in ROUGE-1 and ROUGE-L scores at 15% skipping rate.

Our experiments conclude the optimal skipping rate is around 15%, which maintains more than 80% of the original model performance (for WMT English-to-German and CNN/DM) and 75% of the original model performance for WMT English-to-Chinese - such a skipping level yields approximately 10-12% improvement in TPOT.

| Model Type | | ~Skipping (%) | En | English-to-German | | | English-to-Chinese | | |
|--------------------------|-------------|---------------|--------|-------------------|-------|--------|--------------------|-------|--|

| | R | 35 | 3.92 | 0.51 | 22.88 | 3.87 | 1.05 | 21.24 | |
| | R + L | 15 | 38.01 | 17.89 | 82.14 | 48.35 | 26.57 | 68.63 | |
| | R | 15 | 28.83 | 11.80 | 67.74 | 17.55 | 8.68 | 42.76 | |
| Our Solution (FiPST) | R + L | 25 | 17.84 | 4.14 | 34.95 | 35.79 | 15.66 | 56.92 | |
| | R | 25 | 9.67 | 1.37 | 26.01 | 11.01 | 3.23 | 25.45 | |
| | R + L | 35 | 6.39 | 0.42 | 19.96 | 15.66 | 3.95 | 26.8 | |
| | R | 35 | 3.70 | 0.14 | 21.41 | 6.13 | 1.54 | 22.89 | |

Table 1: Quality Analysis on WMT (English-to-German and English-to-Chinese): BLEU-1, BLEU-2 and COMET scores for varying skipping % have been reported. Here, R + L corresponds to Router Augmentation followed by LoRA fine-tuning and R corresponds to router only (in the proposed FiRST framework). FiRST with finetuning, improves upon the input-agnostic baseline of Unified Skipping for all skipping levels - the improvement is more pronounced for English-to-German.

| Model Type | ~ Skipping (%) | English-to-German TPOT | English-to-Chinese TPOT | Model Ty | e ~Skipping (%) | CNN/DM TPOT |
|--------------|----------------|---------------------------|----------------------------|------------|-----------------|----------------|
| Base + LoRA | 0 | 1x | 1x | Base + LoF | RA 0 | 1x |
| R + L | 15 | 0.90x | 0.88x | R + L | 15 | 0.88x |
| R + L | 25 | 0.82x | 0.83x | R + L | 20 | 0.81x |
| R + L | 35 | 0.69x | 0.68x | R + L | 27 | 0.76x |

Table 2: TPOT variation on WMT (left) and CNN/DM (right) for FiRST. These values are relative to LoRA fine-tuned base model. Fine-tuning is able to improve both TPOT and quality significantly.

| Model Type | 2 | ~Skipping (%) | BERT F1 | Rouge-1 | Rouge-L |
|--------------------------|-------------|---------------|---------|---------|---------|
| Original Model (no skin) | Base + LoRA | 0 | 84.87 | 28.46 | 16.99 |
| Original Would (no skip) | Base | 0 | 82.29 | 23.49 | 14.66 |
| | R + L | 15 | 84.25 | 24.35 | 14.30 |
| | R | 15 | 80.30 | 16.61 | 10.95 |
| Unified Lover Skinning | R + L | 20 | 82.93 | 22.30 | 13.37 |
| Unneu Layer Skipping | R | 20 | 80.32 | 16.51 | 11.15 |
| | R + L | 27 | 80.28 | 15.94 | 9.89 |
| | R | 21 | 77.43 | 10.97 | 7.68 |
| | R + L | 15 | 85.14 | 31.80 | 20.13 |
| | R | 1.5 | 81.25 | 20.20 | 13.01 |
| Our Solution (FiPST) | R + L | 20 | 82.80 | 27.65 | 17.84 |
| Our Solution (FIKS1) | R | 20 | 79.32 | 16.28 | 10.85 |
| | R + L | 27 | 77.50 | 14.65 | 10.45 |
| | R | <u></u> | 75.60 | 9.39 | 6.92 |

Table 3: Quality Analysis on Summarization (CNN/DM dataset): BERT F1, Rouge-1 and Rouge-L scores are
reported for varying skipping levels. FiRST with fine-tuning, improves upon Unified Skipping for all skipping
levels on both Rouge-1 and Rouge-L and is competitive on BERT F1.

7 CONCLUSION

We provide a new algorithm and framework FIRST for layer selection corresponding to input sequence and task towards reducing latency in a quality aware manner. This operates in a KV cache compatible manner and handles batches of sequences, which are drawbacks in many existing work on early exit. We show significant reduction in latency with low degradation of quality on multiple tasks on well known open source datasets and demonstrate superior quality and latency over input agnostic baselines. In the future, we would like to extend our method to 1) improve the optimality of selection of layers, and 2) learn dynamically as new input sequences and tasks arrive.

The expected translation or 684 summary is appended after the ### Response section, making the model predict the response tokens 685 following the "Response:n". 686 687 A.3 LAYER-WISE SKIPPING STATISTICS 688 689 Tables 5, 6, and 7 indicate the fraction of sequences that skip a particular block during the task. If

Tables 5, 6, and 7 indicate the fraction of sequences that skip a particular block during the task. If
the corresponding cell in a row shows a value of 0.8, it implies that 80% of the sequences skip this
block. It is important to note that the decision regarding which block to skip varies across different
datasets and tasks. Additionally, partial skipping in some blocks, with varying percentages, suggests
that while some sequences consider the layer important, others do not and therefore skip it during
the decoding phase.

Figures 4, 5, and 6 illustrate how various blocks are skipped when the model is adjusted to skip approximately 15% of the layers. These plots highlight which blocks are skipped more frequently, depending on the specific task and dataset being used.

Table 7: CNN/DM: Skipping variation with Non-skip Penalization Loss coefficient α

864 A.4 DETAILED RESULT TABLE

Tables 8 and 9 present the detailed results of the machine translation task, reporting scores on all four BLEU metrics (BLEU-1, BLEU-2, BLEU-3, BLEU-4) and COMET. These tables highlight the performance across skipping percentages.

Table 10 indicates the improvement in average time to generate output tokens, specifically for the
 TPOT on GPU under both the router-only and LoRA+router configurations. Note that the latency
 improvement is significantly better in the LoRA+router case compared to the router-only case. Since
 the router model is not fine-tuned for the specific task, the number of tokens generated may vary.

Given that our solution applies skipping only during decoding, observing token generation during this phase is essential to evaluate TPOT improvements. Once LoRA is fine-tuned, the model generates more appropriate responses, resulting in a visible enhancement in TPOT.

| Model Type | | ~Skipping (%) | BLEU-1 | BLEU-2 | BLEU-3 | BLEU-4 | COMET |
|--------------------------|-------------|---------------|--------|--------|--------|--------|-------|
| Original Model (no skip) | Base + LoRA | 0 | 56.94 | 35.56 | 23.19 | 16.02 | 82.66 |
| Original Woder (no skip) | Base | 0 | 38.02 | 22.46 | 13.85 | 9.14 | 68.95 |
| | R+L | 15 | 46.61 | 25.01 | 14.33 | 8.99 | 69.58 |
| | R | 15 | 27.28 | 13.35 | 7.08 | 4.25 | 54.57 |
| Unified Lever Skinning | R+L | 25 | 34.90 | 15.75 | 7.70 | 4.46 | 50.59 |
| Unneu Layer Skipping | R | 25 | 17.74 | 7.35 | 3.52 | 2.06 | 38.74 |
| | R+L | 35 | 7.51 | 2.10 | 0.74 | 0.37 | 20.25 |
| | R | 35 | 3.87 | 1.06 | 0.37 | 0.20 | 21.24 |
| | R+L | 15 | 48.35 | 26.57 | 15.80 | 10.27 | 68.63 |
| | R | 15 | 17.55 | 8.68 | 4.70 | 2.83 | 42.76 |
| Our Solution (FiRST) | R+L | 25 | 35.79 | 15.66 | 7.99 | 4.77 | 56.92 |
| | R | 25 | 11.01 | 3.23 | 1.15 | 0.58 | 25.45 |
| | R+L | 35 | 15.66 | 3.95 | 1.43 | 0.75 | 26.80 |
| | R | 35 | 6.13 | 1.54 | 0.42 | 0.20 | 22.89 |

Table 8: English-to-Chinese: BLEU and COMET scores for varying skipping %

| Model Type | • | ~Skipping (%) | BLEU-1 | BLEU-2 | BLEU-3 | BLEU-4 | COMET |
|--------------------------|-------------|---------------|--------|--------|--------|--------|-------|
| Original Madel (no skin) | Base + LoRA | 0 | 41.78 | 21.74 | 12.30 | 6.93 | 93.00 |
| Original Woder (no skip) | Base | 0 | 37.17 | 18.57 | 10.09 | 5.71 | 87.13 |
