SPEAR: A Structure-Preserving Manipulation Method for Graph Backdoor Attacks

Anonymous Author(s)

Abstract

Graph Neural Networks (GNNs) are vulnerable to backdoor attacks, where adversaries implant malicious triggers to manipulate model predictions. Existing graph backdoor attacks are susceptible to defense mechanisms or robust classifiers because they rely on subgraph injection or structural perturbations, e.g., creating additional edges to attach backdoor triggers to the original graph. To enhance the stealthiness of graph backdoors, we propose SPEAR, a novel structure-preserving graph backdoor attack that avoids modifying the graph's topology. SPEAR operates within a limited attack budget by selectively perturbing node attributes while ensuring the triggers exert significant influence through a global importance-driven feature selection strategy. Additionally, a neighborhood-aware trigger generator is employed to underpin a high attack success rate by utilizing semantic information from the neighborhood. SPEAR amplifies effectiveness and stealthiness by combining subtle yet impactful attribute manipulation with a refined trigger generation mechanism. Extensive experiments demonstrate that SPEAR achieves state-of-the-art effectiveness in bypassing defenses on realworld datasets, establishing it as a potent and stealthy backdoor attack for graph-based tasks.

1 Introduction

Graph Neural Networks (GNNs) have become an indispensable tool for learning and extracting insights from graph-structured data [2, 24, 31, 40], which is prevalent in many real-world domains such as social networks, molecular biology, and financial systems [3, 10, 15,

42]. The core mechanism that drives the success of GNNs is messagepassing, where the model iteratively aggregates information from each node's neighbors, producing node representations that encode both local structure and feature information. This capability has led GNNs to excel in various tasks, including node classification, graph classification, and link prediction [16, 17, 34, 35], etc. 59 60

Recent research [7, 32, 37] has shown that GNNs are vulnerable to backdoor attacks, which pose significant threats in sensitive applications like fraud detection, cybersecurity, and healthcare. In backdoor attacks, adversaries implant backdoors by injecting malicious triggers into the target nodes and manipulating the labels of these nodes to a target class. When a GNN is trained on the dataset poisoned with these triggers, it easily learns the association between the trigger and the manipulated class and is named backdoored GNN. When test samples containing the trigger are presented to the backdoored GNN, the backdoor attack is deemed successful if the backdoored GNN misclassifies the test samples associated with the trigger to the target class.

In backdoor attacks, triggers are typically constructed with the basic elements of data samples. Analogously to how pixel-level visual patterns serve as triggers in computer vision [4, 12] and word-level token-based triggers in NLP [21, 22], subgraphs are natural triggers in graph data, where nodes and edges form the fundamental building blocks [7, 32, 37]. For instance, SBA [37] is a pioneering work that uses random or sampled subgraphs as triggers, though its attack effectiveness is limited. GTA [32] introduces a learnable trigger generator, which adapts subgraphs to specific samples, significantly improving attack performance. To evade detection, other approaches such as UGBA [7] and DPGBA [38] integrate regularization terms into thier loss functions, allowing them to bypass certain defense mechanisms. Beyond subgraphbased triggers, other methods such as NFTA [5], perturb both node features and graph structures to implant triggers. The implantation of these triggers is typically categorized as local neighborhood manipulation.

While existing graph backdoor attacks have demonstrated strong performance, implanting triggers via local neighborhood manipulation may hinder their stealthiness, i.e., the ability to remain undetected and bypass defense mechanisms. The effectiveness of the local neighborhood manipulation relies on the malicious edges that link the triggers to the clean graph. Unlike the continuous and subtle perturbations typical of attribute manipulation, these edges are discrete and structurally conspicuous, making it considerably more challenging to maintain a high level of stealthiness for the attack. These anomalous edges, akin to a *crack in the backdoor*, provide clear entry points for defense mechanisms to exploit. The results of our empirical study in Table 1 indicate that neighborhood perturbation-based attacks are vulnerable to at least one defense strategy, whether anomalous edge detection or robust downstream classifiers.

To overcome these limitations, designing a backdoor attack that 117 implants triggers without altering the graph's topology presents a 118 promising solution to circumvent the creation of anomalous edges. 119 The challenges of developing such an attack lie in two aspects. First, 120 the budget for node attribute manipulation is limited. Although 121 routine in many attacks, performing all-dimensional feature pertur-123 bation or generalization is costly and often infeasible in real-world 124 scenarios where security and privacy are major concerns. For ex-125 ample, in financial systems, where nodes represent participants 126 and edges represent transactions, modifying sensitive attributes such as credit records is impractical and likely to trigger alarms 127 within regulatory systems. Thus, practical constraints demand a 128 smaller attack budget, allowing only perturbations in limited fea-129 ture dimensions. Second, the manipulated node attributes should be 130 reasonable. With a limited attack budget, minimizing modifications 131 is imperative to maintain the trigger's stealthiness and restraining 132 significant semantic changes. 133

To tackle these issues, we propose an approach named SPEAR 134 135 (Structure-PresErving grAph backdooR attack). First, to maximize the efficiency of the attack budget, we focus on effectively selecting 136 poisoned nodes by examining the variety and prediction uncertainty 137 138 of candidate nodes. Second, to ensure that the triggers exert signifi-139 cant influence over the downstream classifier and generalize well to unseen nodes, we implement a global importance-driven feature 140 selection strategy to identify the most impactful feature for trigger 141 142 implantation. The structure-preserving manipulation is achieved via a trigger generator that leverages neighborhood-aware semantic 143 enrichment. In addition, we integrate a self-similarity regulariza-144 tion term into the loss function to promote minimal modifications. 145 In summary, our main contributions can be summarized as follows: 146

- We empirically demonstrate the vulnerability of existing backdoor attacks to robust test models and anomalous edge detection, leading to our proposal of a structure-preserving attack named SPEAR.
- In SPEAR, we introduce a novel node selection method to mitigate antagonistic effects, a global importance-driven feature selection method to enhance the effectiveness of trigger implanting, along with a refined trigger generator to leverage neighborhood information.
- Extensive experiments on real-world datasets with various test and defense models demonstrate that SPEAR outperforms stateof-the-art backdoor attacks.

2.1 Adversarial Attacks against GNNs

Graph Neural Networks (GNNs) have emerged as indispensable tools for complex graph-structured data analysis [18, 27, 29, 30], showing exceptional capability in tasks like node classification and link prediction [31, 34]. Foundational models such as Graph Convolutional Networks (GCN) [16] and GraphSAGE [13] have provided scalable solutions, driving the adoption of GNNs across various fields, including fraud detection, biological systems, and recommendation systems [3, 9, 15, 30, 42]. However, GNNs remain vulnerable to adversarial attacks [8, 32, 37, 43].

Table 1: Attack success rate (%) of backdoor attacks under different defenses on the dataset OGB-arxiv. The underlined results indicate unsuccessful attacks compared with performance without defense.

Adversarial attacks on GNNs exploit the model's inherent vulnerabilities, leading to either reduced accuracy or manipulated predictions [25, 43, 44]. Broadly classified into evasion and poisoning attacks, these methods undermine GNNs at different stages. Evasion attacks occur during the testing phase, where adversaries perturb the graph structure or node attributes of a trained model [26, 28, 33]. Poisoning attacks, on the other hand, target the training phase, where attackers tamper with training data to mislead the model [19, 20, 44].

As a specific type of poisoning attacks, backdoor attacks have emerged as a more insidious threat [32, 37]. These attacks implant triggers that activate malicious behavior only under predefined conditions, making them exceptionally difficult to detect and defend against. This increasing threat elevates the urgency of addressing the growing security concerns surrounding GNNs.

2.2 Backdoor Attacks and Defenses on GNNs

Backdoor attacks implant malicious triggers within training data, causing the model to function normally under standard conditions but to misbehave when encountering trigger-implanted samples. Early approaches, such as in [37], introduced subgraph-based backdoors, which implant universal triggers into training samples. More recent advancements like GTA [32] focus on generating adaptive triggers, tailoring them to individual samples to enhance attack effectiveness. To further improve stealthiness, methods like UGBA [7] and DPGBA [38] incorporate regularization terms in the loss functions, enabling these triggers to evade certain anomalous edge detection mechanisms. NFTA [5], on the other hand, manipulates both node features and graph structure as triggers. However, its reliance on binary feature data limits its adaptability, especially in real-world scenarios where feature types tend to be more complex. Our proposed method is inherently different from these approaches in the following ways: (i) We aim to manipulate the attribute space to generate triggers that avoid producing anomalous edges; (ii) We adopt a novel candidate selection method to adapt the attack to real-world constraints.

In response to the growing threat of backdoor attacks, several defense mechanisms have been proposed. Among these, anomalous edge detection stands out as a promising approach. Prune [7] aims to mitigate the effect of triggers by identifying and removing edges that deviate from the homophily assumption. Another approach, OD [38], leverages an autoencoder-based outlier detection method to identify out-of-distribution edges by filtering those with the

233 highest reconstruction errors. By analyzing prediction variance after removing anomalous edges, RIGBD [39] was developed to 234 235 identify compromised target nodes and mitigate their impact on downstream tasks. Furthermore, robust GNN models such as GN-236 NGuard [36] and RobustGCN [41] have demonstrated resistance 237 to backdoor attacks. Our proposed method is capable of bypassing 238 such defenses as we avoid introducing anomalous edges through 239 structure-preserving manipulation and constrain the magnitude of 240 241 manipulation to prevent substantial semantic shifts.

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{X})$ represent an attributed graph with N nodes, where \mathcal{V} is the node set, $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ is the edge set, and $\mathcal{X} = \{x_1, \ldots, x_N\}$ is the original feature matrix of nodes, where $x_i \in \mathbb{R}^d$ is the node feature of v_i . The adjacency matrix of the graph \mathcal{G} is denoted by $\mathbf{A} \in \{0, 1\}^{N \times N}$, with $\mathbf{A}_{ij} = 1$ indicating an edge between nodes v_i and v_j . The neighborhood of node v_i , including the node itself, is denoted by \mathcal{N}_i . In this paper, we focus on an inductive semi-supervised node classification task, where a small set of nodes $\mathcal{V}_L \subseteq \mathcal{V}$ in the training graph \mathcal{G} are provided with labels from $\mathcal{L} = \{1, \ldots, C\}$, and the test graph $\mathcal{G}_T = (\mathcal{V}_T, \mathcal{E}_T, \mathcal{X}_T)$ is not available during the training stage. Let $\mathcal{Y} = \{y_1, \ldots, y_N\}$ denote the ground-truth labels of nodes in the training graph, with \mathcal{Y}_L and \mathcal{Y}_U denoting the ground-truth labels of labeled and unlabeled nodes, respectively.

3.2 Threat Model

In this paper, following prior studies [32, 37, 38], we focus on graybox backdoor attacks on node classification tasks. In a gray-box scenario, attackers have access to the training data, including node attributes, graph structure, and label information, but lack knowledge of the specific architecture or parameters of the target model. The objective of the backdoor attack is to manipulate the downstream GNN classifier into producing malicious outputs on poisoned samples, while behaving normally on clean ones. To achieve this, attackers poison the training set by implanting triggers into a set of poisoned nodes, then labeling them with the target class. Ideally, this approach ensures that the backdoored GNN associates the trigger with the target label, causing any node containing the trigger to be misclassified as the target class. However, the effectiveness of typical graph backdoor attack lies on introducing malicious edges which can be detected then eliminated by defenses, making it significantly harder to achieve a high level of stealthiness for the attack.

3.3 **Problem Formulation**

We consider a standard semi-supervised inductive node classi-281 fication task in which the goal is to learn a mapping function 282 $f: \mathcal{V} \to \mathcal{L}$, where \mathcal{V} denote nodes in the training graph com-283 prising of labelled nodes \mathcal{V}_L and unlabelled ones \mathcal{V}_U , \mathcal{L} denotes 284 the ground-truth labels, and f is a GNN classifier. Following the 285 standard training scheme of graph backdoor attack, we first poi-286 son the training set by implanting triggers in target nodes before 287 classifier is trained. We denote $\mathcal{V}_P \subset \mathcal{V}_U$ as the poisoned samples 288 selected from unlabelled nodes in the training graph. For each node 289

 $v_i^P \in \mathcal{V}_P$, we transform it into a poisoned sample by implanting trigger in attribute space and alter its ground-truth label as shown in Eq. (1):

$$x_i^P = \text{IMPLANT}(\mathcal{T}_{\phi}(v_i^P), x_i), \quad y_i^P = y_t, \tag{1}$$

where x_i is the original feature, which is transformed into x_i^P after trigger implanting, $\mathcal{T}_{\phi}(\cdot)$ denotes the trigger generator that takes v_i as input, and $y_t \in \mathcal{L}$ is the target label assigned by the attacker. Taking the attack budget into account, the transformation also need to satisfy the following inequality:

$$\sum_{k=1}^{d} \mathbb{I}(x_i[k] \neq x_i^{P}[k]) \le \Delta_D,$$
(2)

where Δ_D is the budget for attribute manipulation, $\mathbb{I}(\cdot)$ is an indicator function, which equals 1 when $x_i[k] \neq x_i^P[k]$. We denote the modified features as \mathcal{D} .

Given a GNN classifier f trained on the poisoned training set, ideally, its behavior is manipulated so that:

$$f(x_j, \mathcal{N}_j) = y_j, \quad f(x_j^P, \mathcal{N}_j) = y_t, \tag{3}$$

for node v_j from an unseen test graph \mathcal{G}_T that is sampled from the same data distribution as the training graph. Following the setting of gray-box attack, the architecture and parameters of f are unknown to the attacker. Therefore, we adopt surrogate model f_{ω} to simulate the downstream classifier. In the empirical risk minimization setting, the objective is to minimize the loss function in Eq. (4) on the training graph:

$$\mathcal{L}_{sur}(\omega,\phi) = \sum_{v_i \in \mathcal{V}_L} l(f_{\omega}(x_i,\mathcal{N}_i),y_i) + \sum_{v_i \in \mathcal{V}_P} l(f_{\omega}(x_i^P,\mathcal{N}_i),y_t),$$
(4)

where ω denotes the learnable parameter of f_{ω} , and $l(\cdot)$ is the cross entropy loss. Our goal is to learn the selection of poisoned nodes \mathcal{V}_P , the selection of feature dimensions \mathcal{D} for trigger implanting, and the trigger generator \mathcal{T}_{ϕ} by solving a bi-level optimization problem:

$$\min_{\mathcal{V}_{P},\mathcal{D},\mathcal{T}_{\phi}} \sum_{v_{i} \in V} l(f_{\omega^{*}}(x_{i}^{P},\mathcal{N}_{i}),y_{t}),$$

s.t.(*i*) $\omega^{*} = \arg\min_{\omega} \mathcal{L}_{sur}(\omega,\phi),$ (5)

(*ii*) $|\mathcal{V}_P| \leq \Delta_P, \ \mathcal{T}_{\phi}(v_i) \in \mathcal{U},$

where Δ_P is the budget of poisoned nodes in training set, and \mathcal{U} denotes all triggers that meet the stealthiness requirement. Considering that jointly optimizing \mathcal{V}_P , \mathcal{D} , and \mathcal{T}_{ϕ} is computationally prohibitive, we break the optimization into two steps. First, we heuristically select poisoned nodes and trigger implanting dimensions as a preprocessing step to approximate the optimal \mathcal{V}_P and \mathcal{D} . Then, we fix these selections to optimize \mathcal{T}_{ϕ} .

4 Methodology

4.1 Overall Architecture of SPEAR

The overall architecture of our framework revolves around three key components, namely poisoned node selection, feature selection, and trigger generator. Effective poisoned node selection is achieved by assessing both the class variety and prediction uncertainty among unlabelled nodes, focusing on those that meet criteria for both effectiveness and stealthiness. To ensure that the

348

291

Conference acronym 'XX, June 03-05, 2018, Woodstock, NY

Figure 1: Overall framework of SPEAR. We use '+' and '-' to denote the annotated labels, with shades of orange and green indicating the corresponding ground-truth labels. During the training phase (blue background), SPEAR selects target nodes \mathcal{V}_P , identifies high global-importance features \mathcal{D} , and optimizes the trigger generator \mathcal{T}_t to produce the poisoned graph \mathcal{G}_P . The downstream classifier is trained on \mathcal{G}_P and is embedded with backdoor consequently. In the inference phase (green background), SPEAR implants triggers into the test graph to manipulate the classifier's predictions.

implanted triggers exert an impactful influence on the downstream classifier while maintaining generalizability to unseen data, we employ a global importance-driven feature selection strategy. This method identifies the most critical feature dimensions for trigger implantation by assessing their overall contribution to the model's prediction. Lastly, the trigger generator is designed to perform structure-preserving manipulations, utilizing semantic information from the neighborhood of poisoned nodes. The generator also incorporates a self-similarity normalization term into the loss function, promoting minimal perturbations to enhance stealthiness. The overall framework is illustrated in Fig. 1.

4.2 Effective Poisoned Nodes Selection

Given the extensive and diverse nature of graph data, the selection of poisoned nodes is critical for ensuring efficient use of the attack budget. Accordingly, the selection of poisoned nodes should adhere to two principles: (i) the chosen nodes should effectively deceive the downstream classifier into associating the trigger with the poisoned label; and (ii) manipulations of these nodes should not have adverse effects on the classifier's performance on clean data.

Therefore, we propose selecting samples with high classification uncertainty within each category as poisoned nodes, which provides several notable advantages. First, sampling from different categories provides class variety which is crucial for successfully implanting targeted backdoor triggers across different class distributions. Second, this approach helps to avoid the creation of strong outliers, thereby mitigating the negative impact on the classifier's generalization, ensuring that the clean accuracy is intact. Besides, robust samples with high classification confidence demonstrate a strong semantic correlation between their attributes and true labels, leading to antagonistic effects between the original attributes and implanted triggers [1, 11], making it more complex for the classifier to learn the mapping between triggers and the target label.

Recall that poisoned nodes are selected from the unlabeled training set \mathcal{V}_U , in order to obtain the uncertainty and pseudo labels, we train a GNN classifier \hat{f}_p on clean data based on Eq. (6):

$$\mathcal{L}_{pre} = \sum_{v_i \in \mathcal{V}_L} l(\hat{f}_p(x_i, \mathcal{N}_i), y_i).$$
(6)

For each node v_i in the training set, its classification uncertainty and pseudo label are calculated as follows:

$$H(v_i) = -\sum_{c \in \mathcal{L}} P_{v_i}(c|\hat{f}_p) \log P_{v_i}(c|\hat{f}_p), \quad \bar{Y}(v_i) = \hat{f}_p(x_i, N_i), \quad (7)$$

where \mathcal{L} denotes label set, and $P_{v_i}(c|\hat{f_P})$ indicates the confidence of $\hat{f_P}$ that node v_i belongs to class c. For nodes assigned with pseudolabel c, we rank them in descending order by their classification uncertainty, as defined in Eq. (7), and denote the resulting sequence as T_c . Given the size of poisoned nodes Δ_P , the final selected node set \mathcal{V}_P can be written as:

$$\mathcal{V}_P = \bigcup_{c \in \mathcal{L}} T_c \left[: \left\lfloor \frac{\Delta_P}{C} \right\rfloor \right]. \tag{8}$$

4.3 Global Importance-Driven Feature Selection

As mentioned in Sec. 1, performing all-dimension manipulation is impractical in real-world scenarios, so we set a budget Δ_D to restrict the number of poisoned features, and introduce \mathcal{F} to denote sensitive features that are not allowed to be modified. Considering that the dimension of node features is typically large for graph data, as shown in Table 2, randomly selecting poisoned features exhibits

SPEAR: A Structure-Preserving Manipulation Method for Graph Backdoor Attacks

Conference acronym 'XX, June 03-05, 2018, Woodstock, NY

high instability and may waste the attack budget. Therefore, we
need to determine which dimensions the triggers should be implanted in. To enhance the influence of the trigger on the prediction
result, we propose selecting the most important features, that is,
the features that contribute the most to the classifier's prediction.
The challenge lies in selecting an appropriate criterion to mea-

The challenge lies in selecting an appropriate criterion to measure the importance of features. One straightforward approach is to compute Shapley values for feature combinations that satisfy the budget for each node individually to decide the candidate feature set. However, it is computationally expensive and fails to generalize to test nodes that are unseen during the training phase. Additionally, inconsistent trigger placement across different nodes can confuse the classifier, weakening its ability to associate the trigger with the target label. Hence, inspired by [6], we aggregate information from all labeled nodes to compute the global importance of each feature, and greedily select the top- Δ_D most important features.

Given the complete feature set \mathcal{D}_a and a GNN classifier \hat{f}_p trained on clean graph, we define the global predictive power of a subset \mathcal{S} as $r(\mathcal{S})$:

$$r(\mathcal{S}) = T - \sum_{v_i \in \mathcal{V}_L} \left[l(\hat{f}_p(x_i^{\mathcal{S}}, \mathcal{N}_i^{\mathcal{S}}), y_i) \right],$$
(9)

. 1

where $S \subseteq \mathcal{D}_a$, *T* represents a constant value for the mean prediction loss of \hat{f}_c , x_i^S denotes the partial feature of node v_i according to S, and $l(\cdot)$ is the cross entropy loss. For each feature *m*, we compute its global importance in Eq. (10) by calculating a weighted average of the incremental changes when adding *m* to subsets S:

$$\phi(m) = \frac{1}{|\mathcal{D}_a|} \sum_{S \subseteq \mathcal{D}_a \setminus \{m\}} \left(\frac{|\mathcal{D}_a| - 1}{|S|} \right)^{-1} \left(r(S \cup \{m\}) - r(S) \right).$$
(10)

After obtaining the global importance of the features, we sort them in descending order and ensure the feature budget and sensitivity constraints are met to obtain the selected feature set \mathcal{D} :

$$\mathcal{D} = (\operatorname*{arg \, sort}_{m} \phi(m) \setminus \mathcal{F})[:\Delta_{d}]. \tag{11}$$

4.4 Neighborhood-Aware Trigger Generator

After deciding on the poisoned nodes \mathcal{V}_P and feature \mathcal{D} , we proceed to implant the triggers into the training set. A key challenge in backdoor attacks is generating effective triggers. We employ sample-specific triggers generated by a learnable generator \mathcal{T}_t , which is parameterized by θ_t . The optimization objective of the trigger generator is equivalent to solving a simplified optimization problem in Eq. (5), formulated as:

$$\min_{\theta_t} \sum_{v_i \in \mathcal{V}_L} l(f_{s^*}(\tau_i, \mathcal{N}_i), y_t)$$

s.t. $\theta_s^* = \arg\min_{\theta_r} \mathcal{L}_{sur}(\theta_s, \theta_t), \ \mathcal{T}_t(v_i) \in \mathcal{U},$ (12)

where θ_s is the learnable parameter of surrogate model f_s and τ_i represents the node feature after trigger implanting. For simplification, we denote the loss function in the upper-level objective as \mathcal{L}_{atk} , which effectively guides \mathcal{T}_t to produce triggers that can generalize to various nodes in \mathcal{V} .

Existing backdoor attacks usually take attributes as input, yet we argue that, in order to boost the trigger's efficacy, the core idea

is to leverage neighborhood information from the target nodes, ensuring the trigger is well-adapted to graph-structured data. For each nodes v_i , its neighborhood-aware encoding can be obtained through an aggregation function:

$$h_i = \text{AGGREGATE}^{(l)}(\{x_u : v_u \in \mathcal{N}_i^{(l)}\}), \tag{13}$$

where $\mathcal{N}_i^{(l)}$ denotes the neighbors of node v_i that are at most l hops away. Using h_i as input, the trigger for the node v_i can be defined as $\mathcal{T}_t(h_i)$. Then we can implant the trigger and obtain the poisoned node attribute τ_i :

$$\tau_i = x_i + \mathcal{T}_t(h_i),\tag{14}$$

where $\mathcal{T}_t(h_i)$ is constrained to be zero outside the features defined by \mathcal{D} . In our experiments, we observe that the choice of aggregation function has a vital influence on the quality of triggers. Optimal performance is achieved when the aggregation function and the surrogate model share the same architecture and parameters. We believe this effectiveness stems from the surrogate model closely simulating the behavior of a backdoored model, thus ensuring that the generated triggers are well-aligned with a manipulated model's decision-making process.

Even though limiting the number of perturbed features enhances the trigger's stealthiness, it still remains essential to further constrain the magnitude of these perturbations to prevent substantial semantic shifts. Thus, we propose a self-similarity loss function, defined as:

$$\mathcal{L}_{sim}(\theta_t) = \sum_{v_i \in \mathcal{V}_P} -\log\left(1 + \alpha \left(1 - \frac{x_i \cdot \tau_i}{\|x_i\|_2 \|\tau_i\|_2}\right)\right), \quad (15)$$

where α controls the contribution of the self-similarity loss.

Combining Eq. (12) and Eq. (15), the final objective can be formulated as follows:

$$\min_{\theta_t} \mathcal{L}_{atk}(\theta_s^*, \theta_t) + \mathcal{L}_{sim}(\theta_t)$$

s.t. $\theta_s^* = \arg\min_{\theta_t} \mathcal{L}_{sur}(\theta_s, \theta_t).$ (16)

Optimizing Eq. (16) directly can be computationally expensive, so we solve it with an alternative optimization schema as [44] does. In inner-level optimization, we update θ_s for *E* iterations on \mathcal{G}_P to accelerate the training process:

$$\theta_s^{(e+1)} = \theta_s^{(e)} - \gamma_s \nabla_{\theta_s} \mathcal{L}_{sur}(\theta_s^{(e)}, \theta_t), \tag{17}$$

where $\theta_s^{(e)}$ is the learnable parameter of surrogate model f_s in the *e*-th iteration, and γ_s is the corresponding learning rate. In upper-level optimization, we fix θ_s and update θ_t using a first-order approximation:

$$\theta_t^{(k+1)} = \theta_t^{(k)} - \gamma_t \nabla_{\theta_t} \left(\mathcal{L}_{atk}(\theta_s^*, \theta_t^{(k)}) + \mathcal{L}_{sim}(\theta_t^{(k)}) \right), \quad (18)$$

where $\theta_t^{(k)}$ is the learnable parameter of the trigger generator \mathcal{T}_t in the *k*-th iteration, γ_t is the learning rate of \mathcal{T}_t , and θ_s^* is he latest value of θ_s obtained from the lower-level optimization. Once θ_t is obtained, we use \mathcal{T}_t to update the poisoned graph \mathcal{G}_P . The detailed training algorithm can be found in Algorithm 1.

5 Experiments

In this section, we empirically analyze the effectiveness and stealthiness of SPEAR on various datasets. Specifically, we aim to answer the following research questions:

- **RQ1:** Does SPEAR outperform the state-of-the-art backdoor models under various defenses?
- **RQ2:** What is the impact of different attack budgets on SPEAR's performance?
- **RQ3:** How do the key components contribute to the attack performance?
- RQ4: How does SPEAR balance training time and performance?

5.1 Experimental Settings

5.1.1 Datasets. To evaluate the effectiveness of our proposed method, we conduct experiments on three widely used datasets, i.e., Cora, Pubmed [23], and OGB-arxiv [14], which correspond to small, medium, and large graphs, respectively. The detailed statistics of these datasets are presented in Table 2.

5.1.2 Baselines. We compare SPEAR against five representative and state-of-the-art graph backdoor attack methods, namely **SBA-Samp**, **SBA-Gen** [37], **GTA** [32], **UGBA** [7], and **DPGBA** [38]. To assess the stealthiness of **SPEAR**, we implement three graph backdoor defenses: **Prune** [7], **OD** [38], and **RIGBD** [39]. Additionally, to validate its stealthiness and transferability, we conduct tests across various models on OGB-arxiv, including prominent GNN architectures such as **GCN** [16], **GraphSAGE** [13], and **GAT** [27], as well as robust GNNs like **GNNGuard** [36] and **RobustGCN** [41]. Comprehensive details regarding these methods can be found in Appendix B.

5.1.3 Evaluation. Following [7, 39], we perform experiments on
the inductive node classification task, where the test graph is unseen by both the attacker and the victim model before inference.
To evaluate effectiveness and evasiveness, we use two metrics: (i)

Table 2: Dataset statistics

Datasets	Nodes	Edges	Features	Classes
Cora	2,708	5,429	1,443	7
Pubmed	19,717	44,338	500	3
OGB-arxiv	169,343	1,166,243	128	40

attack success rate (ASR), which measures the likelihood that the backdoored GNN classifies trigger-implanted nodes into the target class y_t ; and (ii) clean accuracy (CA), which measures the classification accuracy of the backdoored GNN on clean nodes. We randomly mask out 20% of the nodes in each dataset, with half designated as target nodes for assessing attack performance and the other half as clean test nodes to evaluate performance on clean data. The remaining 80% of nodes form the training graph, where 10% of the nodes are used for labeled training and another 10% for validation.

5.1.4 Implementation. For SPEAR, the rate of poisoned nodes in training data is set to less than 1% for each dataset, and the feature budget $\Delta_D = \max(0.02d, 5)$, where *d* is the dimension of node attribute. For baseline attack methods, we adopt the same rate of poisoned nodes, and set the trigger size to 3 with all-dimensional manipulable generated nodes. A two-layer MLP is deployed as trigger generator. As for the surrogate model, a two-layer GCN is used for all attack methods. Each experiment is run five times per architecture, and the average ASR and CA are reported. More details can be found in Appendix A, and the implementation of SPEAR is available at https://anonymous.4open.science/r/SPEAR-48EC.

5.2 Attack Performance

To answer RQ1, we evaluate SPEAR against baseline backdoor attacks across three datasets with or without defenses. To further assess the transferability and stealthiness, we vary the test models from prominent GNN architectures to robust GNNs.

5.2.1 Comparison with Baseline Attacks. Table 3 shows the performance on three datasets against baseline attacks. The top two performances are highlighted in bold and underline. From this experiment, we have the following observations:

- All baseline attacks fail to bypass at least one defense across all datasets, revealing their vulnerabilities. Specifically, SBA-Samp and its variant consistently exhibit lower ASRs, while GTA fails under Prune and OD defenses in most cases. UGBA and DPGBA benefit from specific countermeasures, showing resistance to Prune and OD, respectively, but remain ineffective against other defenses. In contrast, SPEAR shows significantly smaller ASR drops across all defenses, highlighting its superior stealthiness.
- When no defense is applied, SPEAR consistently achieves comparable or better ASR compared with baselines across all datasets, demonstrating its effectiveness. This consistent performance highlights SPEAR's ability to implant effective and impactful triggers without producing anomalous edges.
- SPEAR maintains CA levels similar to the baselines, and often higher than those on the clean graph, both with and without defense methods. This shows that the SPEAR-backed downstream

Table 3: Backdoor attack results (ASR (%) | CA (%)) under different defenses. For clean graphs (Clean), only clean accuracy is reported. The top two performances in terms of ASR are highlighted in bold and underline.

classifier preserves its classification ability in clean samples, further highlighting the stealthiness of SPEAR.

We note that SPEAR's ASR on OGB-arxiv against OD was slightly lower than that of DPGBA by about 4%. This discrepancy can be attributed to DPGBA's distribution-preserving module, which is tailored for out-of-distribution detectors, enhancing its ability to bypass OD. However, this advantage is less effective against other defense mechanisms. In contrast, SPEAR focuses on overall stealthiness, enabling it to demonstrate resilience against a broader range of defenses.

5.2.2 Performance with Different Test Models. Table 4 shows the performance of SPEAR and baseline models with different test models on OGB-arxiv, including three mainstream GNN models (GCN, GAT and GraphSAGE) and two robust GNN models (GNNGuard and RobustGCN), to demonstrate its transferability and stealthiness. From the table, we make the following observations:

• For the two robust GNN models, GNNGuard calculates edge pruning probabilities through a non-linear transformation, while RobustGCN uses Gaussian distributions to represent nodes and employs a variance-based attention mechanism. Results demon-strate that SPEAR is resistant to both GNNGuard and RobustGCN, showcasing its ability to bypass robust GNNs that focus on either graph structure or node attributes.

• SPEAR maintains leading ASR across all test models compared to baseline attacks. Given that we fix the surrogate model to be a 2-layer GCN while varying the test models, such performance demonstrates SPEAR's ability to generate triggers that effectively adapt to different GNN architectures.

5.3 Impact of Attack Budget

To answer RQ2, we conduct experiments to evaluate the sensitivity of SPEAR under different attack budgets. Specifically, for \mathcal{V}_{P} , we vary the ratio of poisoned nodes in the training graph across $\{0.05, 0.1, 0.2, 0.5, 1, 2, 5\}$ %, and for \mathcal{D} , we adjust the ratio of manipulated features to {0.2, 0.5, 1, 2, 5, 10, 15}%, with at least one feature manipulated. Fig. 2 shows the results on Pubmed and OGB-arxiv. We only report attack success rate, as no notable changes in clean accuracy were detected across all baselines and SPEAR. From Fig. 2 we can observe that:

- As the ratio of poisoned nodes grows, SPEAR's ASR shows a consistent increase on both datasets, highlighting that it can effectively leverage a larger attack budget to achieve better results. Meanwhile, SPEAR maintains an ASR above 89% even with a poisoned node ratio as low as 0.05%, showcasing its efficient use of the attack budget.
- When varying the ratio of features budget \mathcal{D} , similar trends are observed. The ASR increases steadily as the proportion of

Conference acronym 'XX, June 03-05, 2018, Woodstock, NY

Figure 2: Impact of size of attack budget.

perturbed features grows, indicating that SPEAR benefits from manipulating more features. Even with a feature budget of just 1%, meaning that only 1 out of 128 features is manipulable in OGB-arxiv, the attack remains highly effective. This confirms that SPEAR can still be applied in real-world environments where feature sensitivity is a critical concern.

833 To answer RQ3, we conduct an ablation study to examine the con-834 tributions of the key components in SPEAR: the node selection 835 module, the feature selection module, and the neighborhood-aware 836 mechanism in trigger generation. To evaluate the effectiveness of 837 node selection, we design a variant of SPEAR named SPEAR-RN, 838 which randomly selects poisoned nodes in the training graph. To 839 assess the contribution of the global importance-driven feature 840 selection strategy, we replace the original feature selection module 841 with random selection, naming it SPEAR-RF. We also introduce 842 a variant called SPEAR-NE, where an MLP is used to substitute 843 the aggregation function in Eq. (13) to evaluate the role of the 844 neighborhood-aware mechanism in trigger generation. To guaran-845 tee fair comparisons, hyperparameters for each variant are tuned 846 according to the performance on validation set. Fig. 3 illustrates 847 the results, showing that:

- 848 • We observe a notable drop in ASR for SPEAR-NE compared to 849 SPEAR, with reductions of 22.47% on Cora, 4.48% on Pubmed, 850 and 1.14% on OGB-arxiv. This result highlights the crucial role 851 of the neighborhood-aware mechanism in SPEAR's effectiveness. 852 We infer that the larger benefit observed on Cora arises from 853 its simple local structure and high homophily, which allow the 854 aggregation function to extract more relevant information and 855 thus enhancing trigger generation. 856
- SPEAR achieves higher ASR than its variants, SPEAR-RN and 857 SPEAR-RF, affirming the contributions of both the node selection 858 and feature selection modules. We notice that the advantage of 859 the global importance-driven feature selection method becomes 860 more pronounced as the feature size increases. This suggests that 861 the method is highly effective at identifying influential features 862 from large candidate sets, a critical capability for datasets with a 863 large number of features. 864

5.5 Trade-off between Time and Performance

To answer RQ4, we conduct experiments examining the trade-off between the training time of the trigger generator and the average ASR on Pubmed and OGB-arxiv. We compute the average ASR both

Figure 3: Comparisons between SPEAR and its variants.

with and without defenses, following the setup in Sec. 5.2.1. For the learnable trigger generators in SPEAR, DPGBA, UGBA, and GTA, the same number of training epochs is used. On OGB-arxiv, we adopt the simplified version of DPGBA, which is designed to handle large-scale graphs. The experiments are performed on an NVIDIA GeForce RTX 4090 with 24GB of memory, and the results are shown in Fig. 4. Compared to other attacks with similar or shorter training time, SPEAR significantly outperforms SBA-Gen and GTA in terms of average ASR. In contrast, DPGBA and UGBA require considerably more time for training the trigger generator, e.g., DPGBA takes 391.98 seconds on Pubmed, making them 50.51× and 4.84× slower than SPEAR, respectively. Overall, SPEAR strikes a superior balance between attack success rate and training efficiency, making it a more practical choice for real-world applications.

Figure 4: Training time of trigger generator vs. performance

6 Conclusion

In this work, we propose SPEAR, a novel structure-preserving backdoor attack designed to exploit the vulnerabilities of GNNs while minimizing the risk to be detected. Unlike traditional backdoor attacks that rely on structural perturbations, SPEAR preserves the graph's topology, focusing instead on perturbing node attributes. By leveraging novel selection methods and neighborhood-aware trigger generation, SPEAR effectively balances attack success rate and stealthiness, making it particularly suited for sensitive graphbased applications. Through extensive experiments on real-world datasets, we demonstrated that SPEAR consistently outperforms existing methods in both effectiveness and stealthiness, even under rigorous defense mechanisms. Our work highlights the significant threat posed by stealthy, structure-preserving backdoor attacks, particularly as GNNs are increasingly deployed in security-sensitive domains. Future research may explore further optimizations in trigger generation and investigate defenses specifically tailored to detect such attribute-focused backdoor attacks.

1045 A Detailed Implementation

A.1 Hyperparameters

All hyperparameters are tuned based on the loss and accuracy of the validation set. For SPEAR, the parameter α , which controls the contribution of the self-similarity loss, is tuned from {0.1, 1, 3, 5, ..., 15}, and E, the number of repeated iterations for inner-optimization, is tuned from {1, 3, 5, 7, 9, 11}. A 2-layer GCN is deployed as \hat{f}_p , and a 2-layer MLP is used as the trigger generator, both with hidden dimensions set to 32. Another 2-layer GCN is deployed as the surrogate model, which also acts as the aggregator providing input for the trigger generator. Its hidden dimension N_h , which determines the level of information compression in the input to the generator, is tuned from {16, 32, 64, 80, 128}. The learning rate γ for the surrogate and trigger generator is tuned from {0.0001, 0.001, 0.005, 0.01]. The ratio of poisoned nodes Δ_P in training set is tuned from {0.5, 1}% for experiments in Sec. 5.2.1, with all baseline attack methods using the same poisoning rate as SPEAR to guarantee a fair comparison. The specific choice of hyperparameters is listed in Table 5 and 6 as follows:

Table 5: Hyperarameter settings for different models.

Model	α	E	Δ_P
GCN	0.1	1	0.5
GAT	0.1	1	0.5
GraphSAGE	0.1	1	0.5
GNNGuard	1	2	1
RobustGCN	5	2	1
Prune	1/1/5	2	0.5
OD	5/1/15	3	1
RIGBA	1/1/5	3	1

Table 6: Hyperparameters settings for different datasets.

Dataset	N _h	γ
Cora	80	0.001
Pubmed	64	0.01
OGB-arxiv	32	0.01

In Table 5, the values separated by '/' correspond to the parameter settings for Cora, Pubmed, and OGB-arxiv, respectively.

A.2 Computing infrastructures

We implement the proposed methods with Numpy 1.26.0, PyTorch 2.2.1 and PyTorch Geometric 2.5.1. We conduct the experiments on a Linux server with an Intel Xeon E5-2680 v4 CPU and a NVIDIA GeForce RTX 4090 GPU with 24GB memory.

B Baselines Information

In this section, we provide a brief overview of the baseline methods used in our experiments.

Anon.

- **SBA-Samp & SBA-Gen** [37]: SBA-Samp injects fixed subgraph triggers, while SBA-Gen enhances this by generating adaptive triggers. These methods face challenges in high ASR and are susceptible to defense mechanisms such as pruning.
- **GTA** [32]: GTA introduces a trigger generator that tailors triggers to specific samples, improving attack effectiveness but vulnerable to several defense mechanisms.
- **UGBA** [7]: UGBA selects poisoned nodes based on representativeness and generates triggers that obey the homophily assumption, maintaining high stealth under a limited budget.
- **DPGBA** [38]: DPGBA improves by ensuring that triggers remain within distribution through adversarial learning, further reducing detectability.
- **Prune** [7]: Prune removes dissimilar edges to disrupt the effectiveness of backdoor triggers by filtering out suspicious connections.
- **OD** [38]: OD leverages autoencoders for outlier detection, identifying and removing out-of-distribution edges to mitigate backdoor attacks.
- **RIGBD** [39]: RIGBD detects poisoned nodes by leveraging random edge dropping and the prediction variance, offering strong defense while maintaining high clean accuracy.
- **GCN** [16]: A standard GNN widely used for node classification, serving as a benchmark for graph-based tasks.
- **GAT** [27]: GAT assigns different attention weights to neighboring nodes, enabling more expressive and flexibility without requiring prior knowledge of the global graph structure.
- **GraphSAGE** [13]: GraphSAGE generates inductive node embeddings by sampling and aggregating information from local node neighborhoods.
- **RobustGCN** [41]: RobustGCN models nodes with Gaussian distributions and employs a variance-based attention mechanism to reduce the spread of adversarial attacks through the network.
- **GNNGuard** [36]: GNNGuard dynamically reweights edges based on cosine similarity, pruning adversarial connections and improving the model's robustness against attacks.
