WASA: WAtermark-based Source Attribution for Large Language Model-Generated Data

Anonymous ACL submission

Abstract

The impressive performances of *large language* models (LLMs) and their immense potential for commercialization have given rise to serious concerns over the intellectual property (IP) of their training data. In particular, the synthetic texts generated by LLMs may infringe the IP of the data being used to train the LLMs. To this end, it is imperative to be able to (a) identify the data provider who contributed to the generation of a synthetic text by an LLM (source attribution) and (b) verify whether the text data from a data provider has been used to train an LLM (data provenance). In this paper, we show that both problems can be solved by watermarking, i.e., by enabling an LLM to generate synthetic texts with embedded watermarks that contain information about their source(s). We identify the key properties of such watermarking frameworks (e.g., source attribution accuracy, robustness against adversaries), and propose a WAtermarking for Source Attribution (WASA) framework that satisfies these key properties due to our algorithmic designs. Our WASA framework enables an LLM to learn an accurate mapping from the texts of different data providers to their corresponding unique watermarks, which sets the foundation for effective source attribution (and hence data provenance). Extensive empirical evaluations show that our WASA framework achieves effective source attribution and data provenance.

1 Introduction

Large language models (LLMs) (Ouyang et al., 2022; Touvron et al., 2023a) have recently demonstrated remarkable performances and hence received a surging interest. These LLMs, trained using massive text data, have displayed impressive text generation abilities. This has given rise to the immense potential of adopting LLMs generated texts for commercial use. However, this potential commercialization has led to major concerns regarding the *intellectual property* (IP) of

training data for LLMs because the texts generated by an LLM may infringe the IP of the data being used to train the LLM. These concerns have been reflected by the increasing regulations on data protection related to AI models. For example, the Coalition for Content Provenance and Authenticity has stressed the necessity of certifying the *source* of online content produced by generative models (Rosenthol, 2022). Therefore, it is of crucial importance for LLMs to be equipped with **source** attribution and data provenance for their generated synthetic texts.

In source attribution, given some synthetic texts generated by an LLM, its aim is to find the source responsible for the generation of these texts. That is, if the data from a data provider has been used to train the LLM and contributed to the generation of a sentence by the LLM, then source attribution identifies this data provider. Moreover, source attribution also improves the interpretability of LLM-generated texts: For example, if the generated content from an LLM is attributed to a trustworthy source (e.g., a peer-reviewed academic paper), then the user is likely to consider the content more reliable. The ability to perform source attribution also endows the LLM with the capability of **data provenance**. Specifically, a data provider can check the source of the generated texts from an LLM via source attribution, and hence verify whether its data has been used to train the LLM, as detailed in Sec. 3.4. This has important implications for data protection. As an example, patients who refuse to have their medical data used for training an LLM for medical diagnosis (due to privacy concerns) may request their data provenance to check whether their data has been misused.

To perform source attribution (and hence achieve data provenance) for LLM-generated synthetic texts, a natural solution involves *watermarking*, i.e., by enabling the LLM to generate synthetic texts with embedded watermarks that contain in-

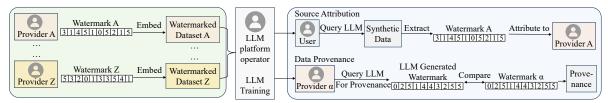

Figure 1: Illustration of WASA's problem setting. Watermarks are embedded into the texts from data providers for training the LLM. The LLM produced by our WASA framework can generate synthetic texts with embedded watermarks that allow for effective source attribution and data provenance.

formation about their source(s). Consequently, source attribution can be performed by examining the watermarks embedded into the generated texts. Our problem setting (Fig. 1) involves 3 parties: data providers contributing text data that may be used for LLM training, an honest third-party LLM platform operator producing an LLM with generated texts that embed watermarks (hence allowing for source attribution), and users of the texts generated by this LLM. The users may request source attribution for the LLM-generated synthetic texts to find out which data provider is responsible for the generated texts, while the data providers may request data provenance to verify whether their contributed data has been used to train the LLM. We consider scenarios where each data provider contributes ample balanced data with unique characteristics, i.e., the data from different data providers exhibit dissimilarities. This encompasses a wide variety of real-world scenarios: For example, online articles written by different authors (i.e., data providers) usually feature their unique writing styles. On the other hand, we do not consider individual documents/sentences as data providers since they have insufficient data.

A watermarking framework capable of effective source attribution has to satisfy some key properties: The watermarking framework should (1) achieve accurate source attribution, (2) be robust against malicious attacks on the watermarks, (3) preserve the performance (i.e., text generation ability) of the LLM, (4) be scalable to a large number of data providers, (5) ensure that the generated watermarks are **transferable** to (i.e., persist after being used as training data for) other LLMs, and (6) be adaptable to fit different LLMs. Sec. 2 discusses these key properties in more detail. To this end, this paper introduces a WAtermarking for Source Attribution (WASA) framework which, to our best knowledge, is the first watermarking framework capable of producing LLMs whose generated texts allow for effective source attribution. Our WASA framework assigns a unique watermark

(i.e., imperceptible to human eyes) to every data provider, and enables an LLM (coined as WASA-LLM) to learn an accurate mapping from the texts of different data providers to their corresponding watermarks (Sec. 3). So, if a data provider is responsible for generating a sentence, then our WASA-LLM is able to include the unique watermark of this data provider in this generated sentence, which naturally supports source attribution. Our contributions are summarized below:

- We propose to use watermarking for source attribution (and data provenance) on LLMgenerated synthetic texts and identify the key properties of such watermarking frameworks.
- We introduce the WASA watermarking framework which satisfies these key properties and is hence capable of producing LLMs whose generated synthetic texts allow for effective source attribution.
- We perform extensive empirical evaluations (Sec. 4) to verify that our WASA framework satisfies these key properties and achieves effective source attribution (and data provenance).

2 Key Properties of Watermarking for Source Attribution

Here, we will discuss the key properties a watermarking framework has to satisfy to achieve effective source attribution (and hence data provenance), as well as how our WASA framework satisfies them. Accuracy. Watermarks should allow for accurate source attribution. Our WASA framework achieves this by training the WASA-LLM to map texts from different data providers to their respective watermarks. Specifically, watermark prediction (using texts) involves training WASA-LLM using watermarked texts (Sec. 3.1) and separating the prediction/generation spaces for the texts and watermarks to both reduce the complexity of watermark prediction (Sec. 3.2) and explicitly enforce watermark generation in LLM-generated synthetic texts (Sec. 3.3). As empirically verified in Sec. 4.1, our framework can achieve accurate source attribution. **Robustness.** Watermarks should be robust against malicious attacks. Since our trained WASA-LLM is able to learn an accurate mapping from the texts to the watermarks as mentioned above, (a) it can be exploited to *regenerate* the watermarks using the (cleaned) generated texts after their watermarks are tampered with (even when the generated texts are under other additional attacks), and (b) it is still able to generate the correct watermarks even if the input texts (prompts) are perturbed. As empirically verified in Sec. 4.2, our WASA framework is indeed robust against these types of attacks.

Scalability. The watermarking framework should cater to a large number of data providers. Since we assign to each data provider a watermark of 10 characters with each selected among 6 Unicode characters (Sec. 3.1), we can represent over 60 million unique watermarks/data providers. Our WASA-LLM's ability to learn accurate texts-to-watermarks mapping ensures that its source attribution remains accurate with more data providers, as empirically verified in Sec. 4.3.

Performance Preservation. Watermarks should (a) not significantly degrade the text generation ability of the LLM (b) nor affect the readability of the LLM-generated synthetic texts too much. To preserve (a), our WASA-LLM only requires a *small number of watermarks* to be embedded into the training text data in order to achieve accurate source attribution, as validated in App. G.2. The watermarks are carefully designed (Sec. 3.1) to achieve (b), as shown in App. H.1.

Transferability. After the generated watermarked texts are used as training data for other LLMs, their generated texts should preserve the watermarks. Our WASA framework achieves this by ensuring that the watermarked data used to train our WASA-LLM has the same structure as the generated watermarked data (i.e., they both embed a 10-character watermark). This allows our generated watermarked data to be readily used as the training data for other LLMs.

Adaptability. The watermarking framework can be easily adapted to fit different LLMs. Our WASA framework satisfies this because it only requires mild modifications to the LLMs and can hence adopt a wide variety of LLMs using the transformer architecture. We have empirically demonstrated WASA's adaptability by employing multiple LLMs in our experiments (Sec. 4.1).

We have only listed above the most essential properties of such watermarking frameworks; there

This sentence is embedded with a 10-character watermark.

may be additional considerations depending on the specific applications. In Sec. 3, we will discuss in more detail how our WASA framework satisfies these key properties due to our algorithmic designs.

3 Watermarking for Source Attribution (WASA) Framework

We first discuss in Sec. 3.1 how we design the watermarks and embed them into text data. Then, we introduce in Sec. 3.2 how we use the watermarked texts to train our WASA-LLM and how its design satisfies the key properties discussed in Sec. 2. Finally, we discuss in Sec. 3.3 how our trained WASA-LLM generates synthetic texts with watermarks and in Sec. 3.4 how the generated texts can be used for effective source attribution and data provenance.

3.1 Embedding Watermarks into Texts for LLM Training

To begin with, the LLM platform operator creates and embeds a unique watermark for each data provider's texts.

Design of Watermarks. To scale to a large number of data providers and still preserve the semantic meaning of the texts, we construct the watermarks using Unicode characters which are imperceptible to human eyes (yet can be decoded by machine learning models). Some of these invisible characters have also been adopted in other studies with language models (Boucher et al., 2022). Every watermark is made up of 10 characters, each of which is chosen among the following 6 Unicode characters: U+200B: Zero Width Space, U+200C: Zero Width NonJoiner, U+200D: Zero Width Joiner, U+2062: Invisible Times, U+2063: Invisible Separator, and U+2064: Invisible Plus. We chose these characters because they are found to be invisible on many commonly used platforms. So, these watermarks preserve the semantic meaning of the original texts to human readers (Fig. 2). Also, note that our WASA framework can easily adopt other choices of characters depending on the use cases. Moreover, these 10-character watermarks allow us to construct over 60 million (i.e., 6¹⁰) unique watermarks and hence achieve scalability to a large number of data providers. As shown in App. G.7, reducing the watermark length trades off scalability for source attribution accuracy.

Embedding Watermarks into Sentences. To enable our WASA-LLM to learn the mapping from the texts of different data providers to their watermarks, it is important to only embed watermarks into the sentences that are representative of the unique characteristics of the data providers. To this end, we calculate the term frequency-inverse document frequency (TF-IDF) scores of all sentences from a data provider and select the sentences with the top 20%of the TF-IDF scores (i.e., most representative sentences) for watermarking, which empirically yields the best trade-off of source attribution accuracy vs. text generation performance among different tested proportions, as reported in App. G.2. For every selected sentence, we embed our 10-character watermark at a random position in the sentence, which allows the LLM to learn to map texts of different lengths to the watermarks and also makes it harder for an adversary to remove/modify the watermarks. As empirically verified in App. G.5, our method of selecting sentences for watermarking based on TF-IDF indeed leads to more accurate source attribution than random selection.

3.2 Training WASA-LLM

Here, we consider the practical scenario where the LLM is already pre-trained before being used by our WASA framework, and we refer to our training of the LLM as *second-stage pre-training*. However, our framework can also be used to train an LLM from scratch without modifications.

Preliminaries on LLMs. Denote an unsupervised corpus by D, in which every sequence $s_i = [u_1, u_2, \ldots, u_k]$ is with a block of k tokens. We focus on decoder-only language models (e.g., GPT (Radford et al., 2019), OPT (Zhang et al., 2022), Llama2 (Touvron et al., 2023b)). When presented with a sub-sequence $s = s_i[1:j-1] = [u_1, \ldots, u_{j-1}]$, the LLM predicts $P(u_j)$ using feed-forward operations, as detailed below:

$$h_0 = s \cdot W_e + W_p ,$$

$$h_{\tau} = \operatorname{decoder}(h_{\tau-1}) \text{ for } \tau = 1, \dots, l ,$$

$$z = h_l[j-1] \cdot W_e^{\top},$$

$$P(u_j) = \operatorname{softmax}(z) .$$

$$(1)$$

As shown in (1), tokens are first projected into an embedding space using W_e (with a dimension of vocabulary size V by embedding/hidden dimension E), followed by positional encoding by adding W_p

to yield h_0 . It is then passed through decoders to produce the last hidden state $h_l[j-1]$ which is multiplied by W_e and applied softmax to generate $P(u_j)$. The training objective is to maximize the log-likelihood $L(s_i)$ of a sequence s_i of tokens:

$$L(s_i) = \sum_{j=2}^k \log P(u_j|u_1,\ldots,u_{j-1})$$
 (2) where $P(u_j|u_1,\ldots,u_{j-1})$ (i.e., similar to $P(u_j)$ in (1)) is the probability of j -th token u_j conditioned on the preceding $j-1$ tokens $[u_1,\ldots,u_{j-1}]$. Forward Pass. To ease exposition, we consider one watermark in a block, but our design also supports multiple watermarks. Our 10-character watermark forms a consecutive sub-sequence of 10 tokens. Denote a sequence with an embedded watermark by $s_i' = [u_1,u_2,\ldots,u_t,w_1,w_2,\ldots,w_m,u_{t+1},\ldots,u_{k-m}]$ where $m=10$ and the u 's and w 's are the word and watermark tokens, respectively. There may be sequences s_i' not embedding any watermark. Hereafter, we will use t to denote the token index before the first watermark token.

To begin with, we augment the original vocabulary (of size V) by our V' = 6 watermark characters (Sec. 3.1), which leads to a new vocabulary size of V + V'. That is, the dimension of our modified token embedding matrix W'_e is $(V + V') \times E$ (Fig. 3). For a sequence s'_i , given a sub-sequence $s' = s'_i[1:j-1]$ comprising the first j-1 tokens in s_i' (i.e., comprising either only word tokens or both word and watermark tokens), the same feedforward operations in (1) are applied to s' (except that W_e is replaced by W'_e) to produce h_l . Next, depending on whether the ground-truth j-th token being predicted is a word token u or watermark token w, we adopt two separate prediction spaces (i.e., separate softmax layers). When predicting a word token u, the first V rows of the matrix W'_e are used to form the $E \times V$ matrix $(W'_e[1:V])^{\top}$ as the linear layer. A softmax layer is then applied to produce the predictive distribution $P_u(u)$ of u over the vocabulary of V word tokens:

$$z_u = h_l[j-1] \cdot (W'_e[1:V])^\top,$$

$$P_u(u) = \text{softmax}(z_u).$$
(3)

When predicting a watermark token w, the last V' rows of W'_e are used to form the $E \times V'$ matrix $(W'_e[V+1:V+V'])^{\top}$ as the linear layer. A softmax layer is then applied to produce the predictive distribution $P_w(w)$ over V' watermark tokens:

$$z_w = h_l[j-1] \cdot (W'_e[V+1:V+V'])^\top, P_w(w) = \text{softmax}(z_w).$$
 (4)

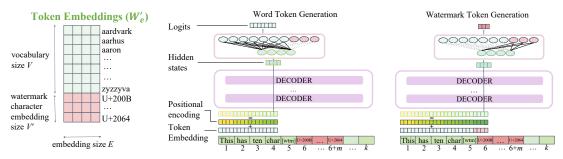

Figure 3: Separation of token embeddings and prediction spaces for texts and watermarks.

This separation of the prediction/generation spaces of the word tokens (3) and watermark tokens (4) allows us to use a small number of additional parameters (i.e., $E \times V'$ instead of $E \times (V + V')$) for watermark prediction based on the hidden states of WASA-LLM. Moreover, this separation allows us to explicitly enforce the generation of watermarks (i.e., using its designated generation space) when we use the trained WASA-LLM to generate synthetic texts, as discussed in Sec. 3.3. Therefore, the watermarks can be regenerated using cleaned texts after being attacked, and the correct watermarks can still be generated even if the input texts (i.e., prompts) are perturbed, hence ensuring the robustness of our WASA framework; more details are in Sec. 4.2.

361

368

371

372

374

377

378

390

391

The two separate softmax layers naturally lead to the following separate log-likelihoods:

$$L_{lm}(s_i') = \sum_{j=2}^{t} \log P_u(u_j|u_1, \dots, u_{j-1})$$

$$+ \sum_{j=t+1}^{k-m} \log P_u(u_j|u_1, \dots, u_t, w_1, \dots, w_m, u_{t+1}, \dots, u_{j-1}) ,$$

$$L_{wtm}(s_i') = \sum_{j=1}^{m} \log P_w(w_j|u_1, \dots, u_t, w_1, \dots, w_{j-1}) (6)$$

$$L_{\text{wtm}}(s_i') = \sum_{i=1}^{m} \log P_w(w_j|u_1, \dots, u_t, w_1, \dots, w_{j-1})$$
 (6)

where $L_{lm}(s_i')$ (5) is the log-likelihood of word tokens, which is split into two sums before and after the watermark tokens, while $L_{\text{wtm}}(s_i')$ (6) is the loglikelihood of watermark tokens, which encourages the LLM to learn texts-to-watermarks mapping.¹ The overall log-likelihood we aim to maximize is therefore $L_{\text{WASA-LLM}}(s_i') = L_{\text{lm}}(s_i') + L_{\text{wtm}}(s_i')$.

The maximization of the log-likelihood of the watermarks conditioned on the texts (6), together with the separation of the prediction/generation spaces, enables WASA-LLM to accurately learn the mapping from the texts to watermarks. This allows us to achieve a high accuracy in source attribution, which will be empirically verified in Sec. 4.1. The backward pass is further elaborated in App. C.

Generating Texts with Embedded Watermarks using WASA-LLM

After our WASA-LLM is trained (Sec. 3.2), it can generate synthetic texts which naturally include both the word and watermark tokens due to their separate prediction/generation spaces. To further improve the alignment between our training and generation stages, we introduce a special token [WTM] which is similar to other specialized tokens and in the vocabulary of V word tokens: When training our WASA-LLM using the watermarked texts, [WTM] is added right before the watermark tokens during tokenization so that the presence of [WTM] indicates that the subsequent m=10 tokens are watermark tokens; when generating texts, if [WTM] is encountered/generated, then it indicates that our WASA-LLM should switch to generating watermark tokens. Specifically, when the token [WTM] is not generated, our WASA-LLM generates word tokens by applying multinomial sampling to P_u (3) which is a distribution over the V word tokens. When [WTM] is generated, our WASA-LLM switches to generating watermark tokens by applying pure beam search to P_w (4) which is a distribution over the V' watermark tokens. After m = 10 watermark tokens have been generated, our WASA-LLM resumes the word token generation. Fig. 9 (App. H.1) shows the WASA-LLM-generated synthetic texts with embedded watermarks, which verifies that the watermarks are imperceptible to human eyes. However, the generated watermarks can be decoded by a watermark decoder algorithm introduced in Sec. 3.4 and hence used for source attribution and data provenance.

Using Watermarks for Source Attribution and Data Provenance

Source attribution and data provenance can be easily performed using the synthetic texts generated by our trained WASA-LLM. When a user requests source attribution for some synthetic texts generated by our WASA-LLM, the LLM platform operator

¹To simplify exposition, for the second sum in (5), when j = t + 1, the term reduces to $\log P_u(u_j|u_1,...,u_t,w_1,...,w_m)$. In (6), when j = 1, the term reduces to $\log P_w(w_j|u_1,\ldots,u_t)$.

uses a designated watermark decoder algorithm to extract the generated watermark from the texts and then attribute these texts to the source (data provider) whose watermark matches the generated watermark (Fig. 1). Meanwhile, the data providers are also given both their own unique watermarks (Sec. 3.1) and the watermark decoder so that they can request their data provenance. Specifically, when a data provider wants to check its data provenance, it can firstly use its own text data (without watermark) as the input/prompt to the WASA-LLM to obtain a generated watermark, and then verify whether the generated watermark matches its own watermark (Fig. 1). Details on the matching algorithm are elaborated in App. D.

4 Experiments

We perform extensive empirical evaluations to validate that our WASA framework satisfies the 6 key properties in Sec. 2. The experimental results shown below are the average taken from 5 random seeds. Following that of Clement et al. (2019), we download academic papers from ArXiv and apply post-processing to obtain a cleaned dataset (i.e., detailed in App. E.1) which we call Clean-ArXiv-Corpus (or ArXiv for short). The ArXiv dataset contains academic papers from several categories, each of which is treated as a data provider. We also use the BookSum dataset (Kryściński et al., 2022) consisting of various books, each considered as a data provider. We adopt 10 data providers for each dataset in our main experiments and show that our WASA can scale to a larger number (up to 100) of data providers in Sec. 4.3. We obtain WASA-LLM from our second-stage pre-training (Sec. 3.2) of the pre-trained GPT2-Large, OPT-1.3B, and Llama2-7B. App. E gives more details on the datasets and model training. Fig. 4 in App. E.2 shows the training convergence of WASA-LLM in terms of the losses for word and watermark tokens.

4.1 Accuracy

To facilitate easy evaluations of the source attribution **accuracy**, for each data provider, we use the sentences selected for watermarking (after removing the watermarks) as the inputs/prompts to the trained WASA-LLM, and use the watermarks embedded into the generated texts for source attribution. This simplifies the evaluations because the corresponding data provider of the input sentence is naturally the ground-truth source. Specifically, we first select 50 sentences from each data provider

(i.e., 50 trials). Next, we use the first 200 characters of every selected sentence (without watermarks) as the input/prompt to the trained WASA-LLM which then generates synthetic texts (by continuing the sentence) with a token length of 100. More details are in App. F.1. The watermark embedded into the generated sentence is then used for source attribution, i.e., the source attribution is correct if this watermark matches the watermark of the data provider corresponding to this sentence (Sec. 3.4). As a result, for every data provider, the accuracy of source attribution is calculated as

$$accuracy = \frac{number\ of\ correct\ watermarks}{number\ of\ trials}.(7)$$

To mitigate the impact of the length of the generated sentence on our evaluations (i.e., a watermark may not be generated if the generated sentence is too short), we use a simple technique to enforce watermark generation: If a watermark is not generated, then we force the generation of a watermark by adding the token [WTM] to the end of the sentence (Sec. 3.3). This is only adopted to simplify the evaluations; as verified in App. G.3, naturally generated and forcefully generated watermarks lead to comparable source attribution accuracy. We will also empirically show in App. G.4 that this enforced watermark generation is not necessary if the generated texts are long enough.

Top-k **Source Attribution.** In addition to attributing a generated sentence to a single source by using one watermark, it may be acceptable for some users to attribute a generated sentence to multiple possible sources that contain the true source. To account for these scenarios, we propose top-ksource attribution in which we modify our watermark generation (Sec. 3.3) so that when the token [WTM] is encountered, we generate the top k > 1watermarks with the largest beam search scores. In this case, source attribution is successful if the true watermark is contained in these k watermarks, so the top-k accuracy can be defined by replacing the number of correct watermarks in (7) with the number of generated sentences whose top k watermarks contain the true watermark.

Source Attribution Accuracy. Tab. 1 reports the source attribution accuracy averaged over 10 data providers which implies the accuracy of random guess is 10%. So, our WASA framework consistently achieves accurate source attribution for both datasets and all language models; Tabs. 7 and 8 in App. F.1 gives the source attribution accuracy for

different data providers. We have also performed a fine-grained analysis of the errors incurred by our WASA framework in source attribution. Results in Tab. 10 (App. F.1) suggest that most source attribution errors are caused by generated texts exhibiting the characteristics of multiple data providers. This further substantiates the reliable watermark generation ability of our WASA-LLM since it almost never generates incorrect (unseen) watermarks.

Data Provenance. We will show here that WASA's ability to perform reliable source attribution also allows us to achieve accurate data provenance. When a data provider requests data provenance, it uses its own text data (without watermark) as the input/prompt to our trained WASA-LLM to verify whether the generated watermark matches its own (Sec. 3.4). We consider 20 categories/data providers in the ArXiv dataset, including 10 categories whose data was used for second-stage pretraining of GPT2 to obtain WASA-LLM and 10 other categories whose data was not used. We select 50 papers from each category and choose a sentence from every selected paper to use as the input/prompt to WASA-LLM for generating a watermark. The results in Tab. 9 (App. F.1) show that for the first 10 categories whose data was *not used* to obtain WASA-LLM, we are consistently able to recognize that their data was not misused; for the other 10 categories whose data was used to obtain WASA-LLM, we can also identify this with high accuracy of 74.84% and top-3 accuracy of 95.76%.

4.2 Robustness

Our WASA framework is robust against malicious attacks aiming to disrupt the source attribution. We introduce the threat model as follows: We identify potential attackers as those intending to alter the LLM-generated text to remove IP acknowledgments to data contributors or alter input sentences to disrupt the watermark generation and hence the source attribution results. The attackers do not have access to the LLM itself but can query the model and modify the generated outputs. The attackers may also possess tools that can remove the Unicode characters (hence the watermark) inside a text.

Watermark Removal/Modification Attack. An adversary may remove/modify the watermarks in our generated sentence to sabotage the source attribution accuracy. Due to the ability of our WASA-LLM in learning an accurate texts-to-watermarks mapping, the watermark can be *regenerated* if it is manipulated. Specifically, we clean the generated

sentence by removing the corrupted watermark, and use the cleaned sentence as input/prompt to WASA-LLM to regenerate the watermark (without generating synthetic texts) which is then used for source attribution. The regenerated watermarks by WASA-LLM (from second-stage pre-training of GPT2 on ArXiv dataset) lead to an overall accuracy (top-3 accuracy) of 71.60% (93.76%) which is comparable to the original 74.84% (95.76%) (Tab. 1). So, our watermark regeneration is an effective defense mechanism. Besides removing/modifying the watermark, an adversary may additionally modify the content of the generated sentence:

Additional Attacks. We also consider additional attacks on generated sentences with embedded watermarks and on input sentences, including insertion, deletion, synonym substitution, and syntactic transformation attacks. Tab. 2 reports the source attribution accuracy under the first 3 attacks and App. F.2 reports the accuracy under the last attack along with all the attack descriptions. For such attacks (in addition to watermark removal/modification attacks) on generated sentences, watermark regeneration is used. The results show that although the attacks deteriorate attribution accuracy, high source attribution accuracy can still be preserved. This can again be explained by the reliable texts-to-watermarks mapping of our WASA-LLM, which is robust against perturbations to the input/prompt.

4.3 Scalability

Here, we verify WASA's ability to scale to a large number of data providers. We follow the experimental setup in Sec. 4.1 and increase the number of data providers. Results in Tab. 3 and Tab. 14 (App. F.3) show that as the number of data providers increases, the source attribution accuracy inevitably decreases yet still remains relatively high (especially for the larger Llama2 model) compared with random guessing. With more data providers, we recommend using k>1 in top-k source attribution due to higher resulting accuracy and identifying the true source from among them.

4.4 Performance Preservation

We show that our WASA framework can preserve the ability of the LLM to generate high-quality text in Tab. 15 (with more details in App. F.4) and ensure decent readability of WASA-LLM-generated synthetic text in App. H.1.

Other Key Properties, including Transferability

656

659

In this section, we will review related works on source attribution and data provenance; further discussions on watermarking natural languages and models as well as text steganography are in App. B. Recent studies by Song and Shmatikov (2019) on verifying dataset usage in language model training through membership inference attacks are limited by the model's output length, making them unsuitable for long-generated texts which we have considered in this work. Liu et al. (2023a) have proposed to plant backdoor triggers in training texts to check for data usage, but this method is not robust against removals of the backdoor triggers and can impair text generation performance. Importantly, the above works have only focused on data provenance and cannot be easily adapted to perform effective source attribution. Abdelnabi and Fritz (2021) have embedded messages postgeneration via adversarial training, which means the messages can only be used for IP protection and cannot be used for source attribution during generation. Some recent works in computer vision have tackled the problem of source attribution (Marra et al., 2018; Yu et al., 2019, 2021). However, to the best of our knowledge, effective source attribution for the texts generated by language models remains an open problem and is the focus of our work here.

6 Conclusion

This paper describes our proposed WASA framework which allows for effective source attribution (and hence data provenance) as a solution to intellectual property infringement in the context of LLMs. By embedding unique watermarks into synthetic texts generated by LLMs, WASA not only enhances the reliability and interpretability of LLM-generated content but also provides a crucial tool for data protection, allowing data providers to verify the use of their contributions in LLM training processes. The extensive empirical evaluations of the WASA framework affirm its effectiveness in achieving accurate source attribution and data provenance while satisfying the key properties we have identified above.

Limitations

Since our WASA is the first watermarking framework to achieve effective source attribution for LLM-generated texts, it faces some limitations which may call for future work. Firstly, we have only focused on scenarios where the data providers have balanced data with sufficient dissimilarities. However, in some applications, the data from different data providers may be imbalanced or similar. Secondly, though we have shown that our WASA is robust against various adversarial attacks, it is unclear whether it is robust against more advanced/sophisticated attacks, which may be achieved through adversarial training in future work.

Ethical Considerations

Similar to other research topics on LLMs, watermarking the synthetic texts generated by LLMs for source attribution (and hence data provenance) requires a thoughtful and ethical approach due to its potential societal implications. That is, it is important to take necessary measures to avoid causing harm to certain parties. Potential risks related to our watermarking framework include the following:

- **Privacy Risks.** Watermarking can potentially reveal sensitive information about data providers, thus leading to privacy breaches or the possibility of re-identification if not handled carefully. In our WASA framework, only the watermark can be seen in the synthetic data, which does not directly imply personal information about the data providers. Privacy can be preserved given that the mapping from watermarks to data providers is kept confidential.
- Chilling Effects. Watermarking may discourage some data providers from sharing their datasets, especially if they fear potential misuse or unintended consequences of having their data linked to specific research outcomes.
- Data Manipulation. While watermarks are meant to be unobtrusive and our WASA framework has been shown to be robust against various adversarial attacks, there can be unforeseen real-world instances where malicious actors attempt to manipulate the watermark, which may lead to negative consequences such as the dissemination of altered or misleading information.

To address these potential risks, it is essential to carefully consider the ethical implications of our watermarking framework and implement measures to protect the privacy and interests of all involved parties, particularly those who are more susceptible to harm. Researchers should conduct comprehensive risk assessments and engage in transparent communication with data providers to ensure the responsible and ethical use of watermarked data. Additionally, incorporating diverse perspectives and involving vulnerable communities in the decisionmaking process can help identify and mitigate potential harm effectively.

We have given the necessary details for reproducing the results of our work in this paper. Detailed descriptions of the datasets used and the experimental settings have been included in Sec. 4 and App. E, including the 5 specific random seed numbers for the experiment runs.

B Additional Related Works

In addition to the previous works discussed in Sec. 5 that are most closely related to ours, we will give a review of additional related works on watermarking natural languages and text steganography, as well as recent works on watermarking language models.

Watermarking Natural Language/Text Steganography. In natural language processing, watermarking and steganography are closely related in that they both desire stealthiness and robustness. However, there are also important differences because watermarking emphasizes the importance of ownership, whereas steganography focuses on the secret communication of messages. Language watermarking is used to protect the integrity and authorship of digital texts (Kamaruddin et al., 2018; Podilchuk and Delp, 2001). Early approaches of language watermarking are mostly rule-based and make use of linguistic techniques such as synonym substitution (Topkara et al., 2006b) and sentence structure alteration (Topkara et al., 2006a) to embed watermarks while attempting to preserve the semantic meaning of the original texts. However, these approaches usually lead to deteriorated text quality and are not scalable. Some recent works have aimed to develop advanced text steganography methods using deep learning. The work of Yang et al. (2019) has utilized recurrent neural networks to automatically generate steganographic texts, and the work of Ziegler et al. (2019) has proposed to first convert the secret messages into bit strings and then map them to the cover text based on arithmetic coding with the help of GPT2 (Radford et al., 2019).

Watermarking Language Models. Some recent works have proposed methods to add watermarks to language models in order to protect the IP of the models (Dai et al., 2022; Gu et al., 2023; He et al., 2022; Zhao et al., 2022). These methods allow the verification of model ownership and are hence able to protect the economic interests of model

owners. Specifically, the work of He et al. (2022) has employed lexical replacement to watermark the language model output and used hypothesis testing for post-hoc model ownership verification. The work of Gu et al. (2023) has adopted backdoor attacks to embed black-box watermarks into pretrained language models, which is achieved by using rare words as well as a combination of common words as backdoor triggers and verifying the watermarks by calculating the extraction success rate. Apart from model protection, the work of Kirchenbauer et al. (2023) has proposed to use watermarking to distinguish between human-generated and model-generated synthetic texts, which is achieved by softly constraining the word choices when the model generates synthetic texts and using hypothesis testing to make the distinction. More recently, the work of Kuditipudi et al. (2023) has improved the method from Kirchenbauer et al. (2023) by developing a distortion-free method, which ensures that the watermarks do not change the sampling distribution of the texts. Importantly, these methods cannot be used to perform source attribution for the texts generated by language models, which we focus on in this work.

C Backward Pass

In the main paper, we introduce the forward pass of our model in Sec. 3.2. Here, we delve into the backward pass in our framework. Remember that the most important design of the framework is the separation of the prediction/generation spaces of the word tokens (3) and watermark tokens (4). We represent the overall log-likelihood as $L_{\text{WASA-LLM}}(s_i') = L_{\text{lm}}(s_i') + L_{\text{wtm}}(s_i')$. Notice that maximizing these log-likelihoods is equivalent to minimizing the cross-entropy loss $Loss_{\text{WASA-LLM}}(s_i') = Loss_{\text{lm}}(s_i') + Loss_{\text{wtm}}(s_i')$ in which

$$Loss_{lm}(s'_{i}) = \sum_{j=2}^{t} CE(P_{u}(u_{j}), u_{j}) + \sum_{j=t+1}^{k-m} CE(P_{u}(u_{j}), u_{j}),$$

$$Loss_{wtm}(s'_{i}) = \sum_{j=1}^{m} CE(P_{w}(w_{j}), w_{j})$$
(8)

represent the losses for the word and watermark tokens, respectively. For simplicity, in (8), we omit the conditioning on the preceding tokens in $P_u(u_j)$ and $P_w(w_j)$, which can be found in (5) and (6).

Due to the design above, the backward pass for updating the parameters W'_e in the last linear layer is also separated. That is, the gradients of word token loss $Loss_{lm}(s'_i)$ and watermark token loss $Loss_{wtm}(s'_i)$ (8) are responsible for updating

 $(W'_e[1:V])^{\top}$ (3) and $(W'_e[V+1:V+V'])^{\top}$ (4), respectively. Specifically, the gradient update rule for W'_e (with learning rate α) can be expressed as $W'_e \leftarrow W'_e - \alpha h_l \cdot \nabla_z$ where ∇_z is a (V + V')dimensional gradient vector allowing the separated gradient updates to be easily achieved in a unified manner, as described below. Next, using the respective losses for word and watermark tokens (8), the gradient vectors w.r.t. z_u and z_w are calculated as V-dimensional $\nabla_{z_u} = \partial \text{CE}(P_u(u_j), u_j)/\partial z_u$ and V'-dimensional $\nabla_{z_w} = \partial \text{CE}(P_w(w_i), w_i)/\partial z_w$ respectively. When the loss is calculated from predicting a word token u_i (8), let $\nabla_z = [\nabla_{z_u}, 0_{V'}]$ where $0_{V'}$ is a V'-dimensional all-zero vector. When the loss results from predicting a watermark token w_i (8), let $\nabla_z = [0_V, \nabla_{z_w}]$. Note that for the parameters in the last linear layer which are responsible for predicting the word tokens using the hidden state (i.e., parameters $(W'_e[1:V])^{\top}$ in (3)), the gradient updates are not affected by the loss for the watermark tokens. This helps us to further limit the impact of the added watermarks on the original ability of the LLM to generate high-quality synthetic texts and hence preserve its performance. For the parameters in the other transformer layers (except for the frozen layers), their updates are performed using the gradients w.r.t. the losses for both the word and watermark tokens; see App. E.2 for more details.

Note that both our forward pass and backward pass only require mild modifications to an LLM. Therefore, our WASA framework can be easily adapted to fit a wide variety of LLMs, which ensures its **adaptability** property.

D Watermark Matching

Exact Matching. In this work, we adopt exact matching to determine the correctness of the generated watermarks. That is, given a piece of synthetic text with watermarks and the corresponding ground-truth watermark, the generated watermark is correct only if they are strictly equal in string matching. In addition, in case multiple watermarks are generated in the synthetic data, all generated watermarks have to match the ground-truth watermark to affirm the correctness. The pseudocode for the matching algorithm is given in Alg. 1:

Soft Matching. To further improve the source attribution accuracy in some applications, we may relax the requirement of exact watermarking matching and instead attribute the generated texts to the

Algorithm 1 Exact Matching

```
Require: Synthetic text syn, ground-truth watermark wtm_g
1: if \exists wtm \text{ in } syn \text{ then}
2: wtms \leftarrow watermark decoder(syn)
3: if for all wtm \text{ in } wtms \text{ } wtm == wtm_g
(by string matching) then
4: return True
5: end if
6: end if
```

data provider whose watermark has the smallest Levenshtein distance to the generated watermark. However, in all our experiments, our WASA is able to achieve accurate source attribution without soft matching. 1080

E Detailed Experimental Setup

E.1 Datasets

To simulate different data providers with unique characteristics, we create the Clean-ArXiv-Corpus (or ArXiv for short) dataset which consists of academic papers from ArXiv. The dataset contains academic papers from various sub-disciplines, including computer science, physics, mathematics, public health, and other related fields. We make use of the provided metadata from the work of Clement et al. (2019) to download the corresponding PDF files and retrieve the categorization information associated with each article. Subsequently, we employ GROBID (Lopez, 2008-2023) to parse and extract the main body of the papers, excluding the abstract and reference sections. Our Clean-ArXiv-Corpus dataset covers a comprehensive collection of 100 distinct categories, each comprising a number of papers ranging from 2827 to 2984. We treat every category as a data provider, so one data provider/category is the source of each piece of text. Our main experiments in Sec. 4 are conducted using 10 categories (i.e., data providers) and we use 33% of papers from each category due to computational constraints. However, in our ablation study (App. G.6), we have also tested utilizing more data from every data provider (including 100% of the data), which has led to further improved performances and consistent conclusions. For each of the 10 categories, we further randomly split its data into training and evaluation datasets with a ratio of 9:1 according to the seed number. In our ablation study, we will use more categories and also use all

papers in each category. More detailed information about the full Clean-ArXiv-Corpus dataset, including all 100 categories and all papers in each category, is shown in Tab. 4; Tab. 4 shows an instance of the random split into training and evaluation datasets based on seed number 2023.

In addition to the Clean-ArXiv-Corpus dataset, we also adopt the BookSum dataset (Kryściński et al., 2022). This dataset contains documents from the literature domain including novels, plays, and stories. The BookSum dataset contains 181 books and we treat *every book as a data provider*. For every data provider (i.e., book), we adopt all the text data from the book in all our experiments. More information on the BookSum dataset is shown in Tab. 5; Tab. 5 shows an instance of the random split into training and evaluation datasets based on seed number 2023. Additionally, we have adopted more diverse datasets, details of which are found in App. G.11.

E.2 Experimental Setting

In our experiments, we build our WASA-LLM based on the open-source pre-trained GPT2-Large model (Radford et al., 2019), OPT-1.3B model (Zhang et al., 2022) and Llama2-7B model (Touvron et al., 2023b). Based on the pre-trained weights, we perform our second-stage pre-training (Sec. 3.2) of the pre-trained GPT2-Large model, OPT-1.3B model, or the Llama2-7B model on the watermarked (Sec. 3.1) text data for one epoch to obtain WASA-LLM. We find that training for one epoch al-

ready allows our WASA framework to achieve compelling performances, as shown in our experiments in Sec. 4. We have also tested more training epochs in App. G.8 and the results suggest that our performances can potentially be further improved with more training epochs. We plot the convergence of the training of our WASA-LLM in terms of the losses for the word and watermark tokens in Fig. 4, which shows that our second-stage pre-training effectively reduces both losses. Importantly, the watermark token loss rapidly declines after a small number of steps, which suggests that our WASA-LLM can quickly learn an accurate texts-to-watermarks mapping.

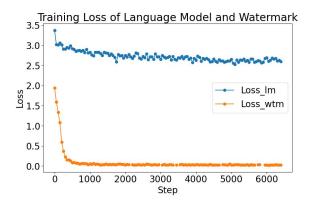

Figure 4: Training losses for word tokens (Loss_lm) and watermark tokens (Loss_wtm) when obtaining WASA-LLM from second-stage pre-training of the GPT2 model on ArXiv dataset.

Here, we give more details on the hyperparameters we adopted. We fix 5 seed numbers at 2021, 2022, 2023, 2024, and 2025 for obtaining reproducible results on GPT2 and OPT models, and 3 seed numbers at 2022, 2023, 2024 for the Llama2 model. The results shown in this work are the average taken across that from the seeds. We adopt the Adam optimizer with a learning rate of 5×10^{-5} and no weight decay. We make use of the fp16 technique and a gradient accumulation of 8 to speed up training. We also adopt a gradient checkpoint to reduce memory usage so that batch size can be slightly increased. We use a block size of 512 and a batch size of 3 for most of the experiments and a batch size of 16 in the experiments to evaluate scalability. To further preserve the ability of the original pre-trained LLM models, during the second-stage pre-training, we freeze the first 12 layers of GPT2-Large (among a total of 36 layers) and freeze the first 8 layers of OPT-1.3B (among a total of 24 layers). For the second-stage

pre-training of Llama2-7B, we adopt LoRA (Hu et al., 2021) and set the rank and alpha to 32, 'q_proj', 'k_proj', 'v_proj', 'o_proj', 'gate_proj', 'gate_proj', 'gate_proj', 'up_proj', 'down_proj' as the target modules, and 'lm_head', 'embed_tokens' as the modules to save. When generating the synthetic texts (see Sec. 3.3), we use the multinomial sampling of top-60 with temperature = 0.7. We also make use of a 1.2 repetition penalty and a 2.0 length penalty to generate better synthetic data. The generation of watermarks for our WASA-LLM adopts a pure beam search, as discussed in Sec. 3.3, with a beam size of 5. For the baseline model used in the ablation studies (i.e., GPT2-Large), watermark generation is performed in the same way as text generation, so we use the same hyperparameters as that specified in the baseline model. All second-stage pre-training is performed using NVIDIA RTX A5000 and A100. In our implementation, we adopt the GROBID library to process the PDF files. For model training, we adopt the Hugging Face Trainer pipeline which embeds necessary tricks to speed up the training process. The open-source GPT2-Large, OPT-1.3B, and Llama2-7B are also adopted from Hugging Face.²

E.3 Effectiveness of Evaluation

In our experiment design, we assign the ground truth source of each generated text to be identical to that of the prompt sentence. Here, we would like to verify that our method of using the source of the prompt sentence as the ground truth source for the generated sentence is indeed a reliable approach, in addition to its benefit of simplifying the experimental evaluation.

A natural and reliable method to find the ground truth source of a generated text is to consult the opinion of human experts. Therefore, we would like to show that our method to determine the ground truth source is an accurate approximation to human evaluations. To avoid the substantial costs and resources associated with human evaluators, we have employed GPT4, noted for its human-level performance across various benchmarks (OpenAI, 2023), as a surrogate 'human-like labeler'. Then, we examine whether the ground truth source determined by our method (i.e., using the source of the prompt sentence) aligns well with those determined by GPT4. Specifically, we use GPT4

to categorize generated texts into one of the ten ArXiv categories (i.e., data providers) using a carefully constructed prompt, as shown in Tab. 6. After evaluating 500 generated texts, we have found that 89.6% of GPT4's decisions align with our source determination method (i.e., using the source of the prompt sentence). This validates that our method to determine the ground truth source of a generated text is a reasonable and reliable approach.

We would like to add that employing GPT4 as a 'human-like labeler' is only feasible in our controlled setting here because it requires prior knowledge about all sources and detailed descriptions of the sources; see the detailed prompt in Tab. 6. Moreover, it also incurs excessive costs in terms of monetary expenses and computations when the number of data providers is large. Therefore, we would like to clarify that this GPT4-based method is not a realistic alternative method for source attribution and is instead only employed here to verify the reliability of our method of source determination.

Additionally, note that the reason why we have used watermarked training data as the prompt sentences in our evaluation is because it leads to simple and reliable evaluations. Here, we justify this using the GPT4-based experiment as well. We use GPT4 to examine the reliability of the ground truth source determination when sentences from two held-out sets are used as the prompt sentences: when the prompt sentences are selected from unwatermarked training data and when the prompt sentences are from the validation data. The results show that when the prompt sentences are selected from unwatermarked training data, 81.6% of GPT4's decisions align with the source of the prompt sentences; when the prompt sentences are from the validation data, the alignment becomes 75.0%. The results suggest that when the sentences from both held-out sets are used as the prompt sentences, our method to determine the ground truth source is still reasonably reliable. However, our ground truth source determination is the most reliable when sentences from watermarked training data are used as the prompt, as we have done in our main experiments. Therefore, the results justify the rationale behind our choice of using watermarked training data as prompts because it enhances the reliability of our source determination and hence the fidelity of our evaluation results.

Definition of Task in Prompts for GPT4 Labeling

Given below are 10 categories for texts from ArXiv papers with their descriptions. Please read the descriptions and classify the provided texts to one of the paper categories.

The 10 categories are: hep-th, hep-ph, quant-ph, astro-ph, cs.CV, cs.LG, cond-mat.mes-hall, gr-qc, cond-mat.mtrl-sci, cond-mat.str-el.

hep-th stands for High Energy Physics - Theory. This category includes research papers which are centered on theoretical concepts and mathematical models in high energy physics.

hep-ph stands for High Energy Physics - Phenomenology. This category includes research papers centered on the application of theoretical physics to high energy physics experiments. quant-ph stands for Quantum Physics. This category includes research papers centered on the theoretical and experimental aspects of the fundamental theory of quantum mechanics.

astro-ph stands for Astrophysics. This category includes research papers centered on the study of the physics of the universe, including the properties and behavior of celestial bodies.

cs.CV stands for Computer Science - Computer Vision and Pattern Recognition. This category includes research papers focused on how computers can be made to gain high-level understanding from digital images or videos.

cs.LG stands for Computer Science - Machine Learning. This category includes research papers focused on the development and implementation of algorithms that allow computers to learn from and make decisions or predictions based on data.

cond-mat.mes-hall stands for Condensed Matter - Mesoscale and Nanoscale Physics. This category includes research papers that focus on the properties and phenomena of physical systems at mesoscopic (intermediate) and nanoscopic scales.

gr-qc stands for General Relativity and Quantum Cosmology. This category includes research papers centered on theoretical and observational aspects of the theory of general relativity and its implications for understanding cosmology at the quantum scale.

cond-mat.mtrl-sci stands for Condensed Matter - Materials Science. This category includes research papers centered on the understanding, description, and development of novel materials from a physics perspective.

cond-mat.str-el stands for Condensed Matter - Strongly Correlated Electrons. This category includes research papers focused on the study of solids and liquids in which interactions among electrons play a dominant role in determining the properties of the material.

Note that you should only include the class in your reply and provide no explanations. Please classify the following sentence into one of the 10 categories, however, if you think that the sentence could be classified into multiple categories, you may give up to 3 most likely categories:

Table 6: Definition of task in prompts for GPT4 labeling.

More Details on Experimental Setup. In our experiments on the source attribution accuracy, for the ArXiv dataset, we select 50 papers from each of the 10 categories (App. E.1) and for every selected paper, we choose the first sentence that has been selected for watermarking (to obtain our WASA-LLM from second-stage pre-training of various pre-trained LLMs, see Sec. 3.1 for more details on how we select the sentences for watermarking) as well as contains at least 200 characters. Similarly, for every book (i.e., data provider) in the BookSum

dataset, we select the first 50 sentences that have been selected for watermarking as well as have at least 200 characters. As a result, for both datasets, we have selected 50 sentences to be used as the inputs/prompts to our WASA-LLM, which corresponds to 50 trials of source attribution for each of the 10 data providers.

Source Attribution Accuracy for Each Data Provider. Tabs. 7 and 8 show the detailed results on source attribution accuracy for the 10 different data providers, in addition to Tab. 1 in Sec. 4.1. The results show that the accuracy remains balanced across the data providers.

Table 8: Source attribution accuracy achieved by our WASA-LLM (i.e., obtained from second-stage pre-training of different models on various datasets) for BookSum dataset.

results for the experiment on data provenance presented in Sec. 4.1 of the main paper. The insights/conclusions drawn from these results have been discussed in Sec. 4.1: Due to its ability to perform accurate source attribution, our WASA framework can also achieve reliable data provenance.

Fine-grained Analysis of Source Attribution Errors. To gain more insights into the behavior of our WASA framework, we perform a more fine-grained analysis of the errors incurred by our WASA framework in source attribution on the ArXiv dataset (i.e., corresponding to the results in Tab. 1). In Tab. 10, for every category (i.e., data provider), we separate the source attribution errors into two types of errors: (a) misclassification in which the generated watermark matches the watermark of another incorrect category, and (b) incorrect watermark in which the generated watermark does not match the watermark of any category. The results in Tab. 10 show that the vast majority of our errors result from misclassification and our WASA-LLM rarely generates incorrect watermarks not belonging to any category. This implies that our source attribution errors are mostly caused by the generated

synthetic texts (conditioned on a sentence from a data provider/category) exhibiting the characteristics of multiple data providers. These results further substantiate the strong and reliable watermark generation ability of our WASA-LLM because it almost never generates incorrect (unseen) watermarks.

F.2 Robustness

F.2.1 Additional Attacks on Generated Sentences with Embedded Watermarks

As discussed in Sec. 4.2, an adversary may additionally modify the content of the generated sentence while removing/modifying the generated watermarks. Here, we will consider insertion, deletion, synonym substitution, and syntactic transformation attacks. In **insertion attacks** on a generated watermarked sentence, either one word is randomly inserted into the sentence (i.e., localized insertion attacks), or various words are randomly interspersed throughout the sentence (i.e., dispersed insertion attacks) (Kamaruddin et al., 2018). For dispersed insertion attacks, we vary the attack strengths by changing the number of inserted words from 5% to 20% of the total number

of words in the sentence. In deletion attacks, some words in the text are randomly deleted. In **synonym** substitution attacks (Kamaruddin et al., 2018), an adversary substitutes some words in the generated sentence with their synonyms while preserving the semantic meaning of the sentence. We again test different attack strengths by varying the percentage of randomly deleted and substituted words. In addition, we also performed the syntactic transformation attack on the generated sentences whereby an adversary transforms the sentences (without altering their semantic meanings) via techniques such as modifying the prepositions, tenses, and other syntax components. Here, we adopt a strong variant of such attacks, which paraphrases the input sentence using the PEGASUS model fine-tuned for paraphrasing (Zhang et al., 2020). The accuracy (top-3 accuracy) after the syntactic transformation attacks is 66.28% (89.56%). The **robustness** of our WASA framework can be validated by the marginal performance degradation in Tab. 2. In addition, the standard deviations for this part of the results in Tab. 2 are reported in Tab. 11.

F.2.2 Attacks on Input Sentences (Prompts)

An adversary may also manipulate the input sentence (prompt) to our trained WASA-LLM to disrupt

watermark generation and hence source attribution. The insertion, deletion, and syntactic transformation attacks are the same as those described in App. F.2.1, except that these attacks are performed on the input sentences here. Similar to App. F.2.1, we vary the attack strengths for these three types of attacks. The results in Tab. 2 show that these attacks also only lead to marginal degradation in the source attribution accuracy. Moreover, under the strong syntactic transformation attacks, the source attribution remains accurate (with an accuracy of 63.00% and a top-3 accuracy of 89.00%), which provides further evidence for the robustness of our WASA framework against attacks on the input sentences. Its robustness against these attacks can again be explained by its reliable textsto-watermarks mapping, which allows our WASA-LLM to consistently generate the correct watermarks even if the prompt is perturbed. The standard deviations for this part of the results in Tab. 2 are reported in Tab. 12.

F.2.3 Character-Level Attacks

Apart from the word-level attacks that additionally modify the content of the generated sentence while removing/modifying the generated watermarks, for the regenerated watermarks, we would also like to explore some character-level attacks on the generated sentences similar to the setting in the work of Gao et al. (2018). These attacks aim to disrupt the original texts at a character level, thus making them stronger than word-level attacks; however, it is also potentially easier to identify such attacks (Li et al., 2023). Specifically, we consider characterlevel insertion, deletion, and character-swapping attacks. We also adopt our regeneration defense after these attacks are applied. Tab. 13 shows the source attribution accuracy for the regenerated watermarks.

As shown in Tab. 13, under these strong character-level attacks, the source attribution accuracy of our watermarks is lowered yet remains decent. In addition, we would like to clarify that since these character-level attacks can heavily influence the original readability of the texts, their feasibility in realistic scenarios may be limited.

F.3 Scalability

In Sec. 4.3, we have verified WASA's scalability to a large number of data providers using the ArXiv dataset. Here, we will also show in Tab. 14 the source attribution accuracy for a larger number of

category	n_wtm	n_match	misclassify	incorrect

books (i.e., data providers) using the BookSum dataset. It can be observed that WASA generally does not scale as well (especially for GPT2 and OPT) on the BookSum dataset as compared to the ArXiv dataset because each data provider in the former offers much less data. It is also noteworthy that the larger Llama2 model produces higher accuracy than the smaller GPT2 and OPT models, especially when the number of providers is larger on the BookSum dataset. Nevertheless, the source attribution accuracy still remains relatively high compared with random guessing. As mentioned in Sec. 4.3, with more data providers, we recommend using k > 1 in top-k source attribution due to higher resulting accuracy and identifying the true source from among them.

F.4 Performance Preservation

Here, we will show that our WASA-LLM preserves the text generation ability of the original LLM by comparing it with the original GPT2-Large model which we denote as *originalGPT*. We apply our second-stage pre-training to originalGPT using the same (but un-watermarked) data from the ArXiv dataset as that used for second-stage

pre-training of the GPT2-Large model to obtain our WASA-LLM. We assess the text generation performance using several commonly used evaluation metrics (with a separate evaluation dataset, as explained in App. E.1): perplexity (i.e., lower is better), and distinct-1 and distinct-2 scores (i.e., higher is better) (Li et al., 2016). The results in Tab. 15 show that the text generation ability of our WASA-LLM is comparable to that of originalGPT, which indicates that our WASA framework preserves the ability of the LLM to generate high-quality texts (Sec. 2).

To further assess the naturalness and coherence of the generated text, we have also employed an evaluation method using a GPT4 zero-shot prompt (i.e., introduced in the work of Yao et al. (2023)) to provide a 1-10 scalar score assessing the text's naturalness and coherence. The evaluation results reveal that the original texts from the training data (i.e., ArXiv papers) achieve an average score of 7.370 in coherency and 7.744 in naturalness, while the text generated by our WASA-LLM attains comparable scores of 7.135 in coherency and 6.926 in naturalness. This indicates that our WASA-LLM preserves the ability to generate coherent and natural

F.5 Transferability

Our generated watermarked text has the same structure as the watermarked text used to train our WASA-LLM: They both embed 10-character watermarks into texts with characters from the same vocabulary. So, our generated watermarked text can be readily used as training data for other LLMs that, like our WASA-LLM, can also generate synthetic text with watermarks. That is, our generated watermarked text is **transferable** to other LLMs as their training data.

F.6 Adaptability

Our WASA framework only requires mild modifications to existing LLMs (Sec. 3.2) and can hence be easily adapted to fit various LLMs. This has been empirically verified by our results in Secs. 4.1 and 4.3 that given the same experimental setup, accurate source attributions can be achieved by WASA-LLM that is obtained from our second-stage pre-training of various LLMs (i.e., GPT2, OPT, Llama2).

G Detailed Results from Ablation Studies

Here, we will present detailed results from our ablation studies. In all our ablation studies, we use second-stage pre-training of the GPT2-Large model on the ArXiv dataset to obtain WASA-LLM.

G.1 Effectiveness of our WASA-LLM Training

We have mainly implemented two important algorithmic designs to help our WASA-LLM learn an accurate texts-to-watermarks mapping (Sec. 3.2): (1) using a designated embedding space for watermark tokens and (2) separating the prediction/generation spaces for the word and watermark tokens. Here, we compare our WASA-LLM with two baselines: tokenizerGPT implementing only the first design of a designated embedding space for watermark tokens, and *originalGPT* (original GPT2-Large) implementing neither design. We apply our secondstage pre-training to both baselines using the same (watermarked) data from the ArXiv dataset which was used for second-stage pre-training of the GPT2-Large model to obtain our WASA-LLM, and evaluate the source attribution accuracy following that of Sec. 4.1. The results in Tab. 16 show that the first design alone does not improve the source attribution accuracy whereas the combination of both designs brings about a significant improvement. This is because merely creating the embedding space for watermark tokens does not help in learning the mapping from the texts to watermarks, and it is of particular importance to combine both designs for our WASA-LLM to perform well. Moreover, our WASA-LLM achieves a significantly better source attribution accuracy at the expense of incurring more computational time. Note that original GPT takes longer training time than tokenizerGPT because

Table 16: Comparison of source attribution accuracy achieved by WASA-LLM (obtained from second-stage pre-training of the GPT2 model) vs. the baseline models on the ArXiv dataset where 'n_wtm' denotes the number of generated sentences with watermark, and 'acc.' denotes the source attribution accuracy. 'random' refers to random guess which incurs an accuracy of 10% since there are 10 categories.

G.2 Impact of Number of Watermarks in Training Data

Here, we will evaluate the impact of the number of watermarks in the training data on the source attribution accuracy achieved by WASA-LLM. Following that of Sec. 3.1, we vary the percentage of sentences selected for watermarking (i.e., top X% of the TF-IDF scores) and evaluate its impact on our WASA-LLM obtained from second-stage pretraining of the GPT2 model on the ArXiv dataset. Fig. 5 (left) shows that as the number of watermarks increases, the source attribution accuracy firstly increases and then declines. This is because an overly small number of watermarks results in insufficient data for learning an accurate texts-towatermarks mapping; meanwhile, if watermarks are added to an excessively large number of sen-

tences, then some of the watermarked sentences may not be representative of the texts from their data providers, which also increases the difficulty of learning the mapping from the texts of the data providers to their unique watermarks (see Sec. 3.1). In addition, Fig. 5 (right) shows that increasing the number of added watermarks in general leads to worse text generation performances (i.e., larger perplexity) of the WASA-LLM. The detailed results are provided in Tab. 17. Moreover, Fig. 6 shows a clearer visualization of the results in smaller percentages.

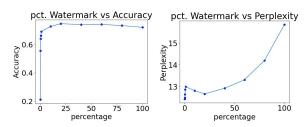

Figure 5: Source attribution accuracy and perplexity achieved by WASA-LLM (i.e., obtained from second-stage pre-training of the GPT2 model on the ArXiv dataset) vs. percentage of watermarked sentences in the training data.

pct. sentences	pct. blocks	acc.	top-3.	perplexity

G.3 Impact of Enforced Watermark Generation

As discussed in Sec. 4.1, to evaluate the source attribution accuracy in our experiments, we have

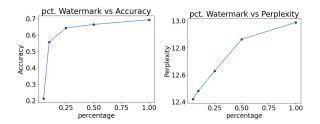

Figure 6: Source attribution accuracy and perplexity achieved by WASA-LLM (i.e., obtained from second-stage pre-training of the GPT2 model on the ArXiv dataset) vs. percentage of watermarked sentences in the training data on a smaller scale of 0.05%-1% for a clearer visualization.

adopted a simple technique to enforce watermark generation in order to simplify the evaluations. That is, if a watermark is not generated after the generation of the sentence is completed, we add the token [WTM] to the end of the sentence to enforce the watermark generation. Here, we will evaluate the impact of this enforced watermark generation. The results in Tab. 18 show that the forcefully generated watermarks and naturally generated watermarks have comparable source attribution accuracy. This shows that the technique of enforced watermark generation we have adopted has minimal impact on the evaluations of the source attribution accuracy (Sec. 4.1).

G.4 Impact of Lengths of Conditioned Sentence and Synthetic Sentence

Recall that in our main experiments, we have used a sentence with 200 characters as the input/prompt (i.e., the conditioned sentence) to our WASA-LLM, and let the WASA-LLM generate synthetic texts with 100 tokens (Sec. 4.1). In this section, we vary the character lengths of both the conditioned sentence and the generated synthetic texts, and evaluate their impact on the source attribution accuracy achieved by WASA-LLM (i.e., obtained from second-stage pre-training of the GPT2 model on the ArXiv dataset). The results in Tab. 19 show that longer conditioned sentences (i.e., inputs/prompts) lead to better performances. Moreover, when the length of the conditioned sentences is fixed (at 200), increasing the length of the generated synthetic texts consistently reduces the number of forcefully generated watermarks (App. G.3) while preserving the source attribution accuracy achieved by WASA-LLM.

G.5 Strategy for Selecting Sentences to Watermark

As we have discussed in Sec. 3.1, for every data provider, we embed watermarks into the sentences with top TF-IDF scores and then use these watermarked sentences for the second-stage pre-training (Sec. 3.2) of the GPT2 model to obtain our WASA-LLM. This is because the sentences with high TF-IDF scores are more representative of the text data from a data provider, which makes it easier to learn the mapping from the texts of different data providers to their corresponding unique watermarks. Here, we will evaluate whether this strategy is effective by comparing it with the natural baseline of randomly selecting sentences to embed watermarks. The results in Tab. 20 show that when selecting 20% of the sentences for watermarking, the strategy of random embedding decreases the source attribution accuracy, which validates the effectiveness of our strategy of selecting sentences with high TF-IDF scores to watermark.

G.6 Impact of Amount of Data for Second-Stage Pre-training to Obtain WASA-LLM

Here, we will evaluate the impact of using varying amounts of data from the ArXiv dataset for our second-stage pre-training (Sec. 3.2) of the GPT2 model to obtain WASA-LLM. As discussed in App. E.1, in our main experiments for the ArXiv dataset, we have used 33% of text data from every category (i.e., data provider) to reduce computations. Here, we will vary this percentage to evaluate its impact on both the source attribution accuracy and the text generation performance achieved by our WASA-LLM. The results in Tab. 21 demonstrate that as more data is used, both the source attribution accuracy and the text generation ability (i.e., perplexity) achieved by our WASA-LLM are generally improved.

G.7 Impact of Length of Watermark

In our main experiments, we have adopted a water-mark design that consists of 10 characters/tokens (Sec. 3.1). However, our WASA framework allows for the use of watermarks with different lengths. Here, we will test the impact of the length of the watermarks on the source attribution accuracy achieved by WASA-LLM (obtained from second-stage pre-training of the GPT2 model on the ArXiv dataset). The results in Tab. 22 show that for water-

category	n_watermark_nf	n_match_nf	accnf	n_watermark_f	n_match_f	accf

marks with 5, 10, and 15 characters, their source attribution accuracies are comparable while the 5-character watermark achieves slightly better performances. This is likely because when the watermark is shorter, the resulting watermark prediction problem becomes relatively easier (i.e., the number of parameters in the last linear layer is smaller), which may lead to better watermark prediction and generation. However, note that a long watermark is favored when there is a need to scale to a large num-

dataset size	acc.	top-3.	perplexity
10%: 100MB	68.80	94.10	14.6135

ber of data providers. Therefore, our WASA framework offers the flexibility to choose watermarks with different lengths, and the preferred watermark length can be application-dependent.

len. watermarks	acc.	top-3.
5 characters	76.12	95.48
10 characters	74.84	95.76
15 characters	74.12	95.28

Table 22: Source attribution accuracy achieved by WASA-LLM (obtained from second-stage pre-training of the GPT2 model on the ArXiv dataset) using watermarks with different lengths.

G.8 Impact of Number of Training Epochs

As we have discussed in App. E.2, we have trained our WASA-LLM for one epoch during the second-stage pre-training (Sec. 3.2). Here, we will evaluate the performance of WASA-LLM after training with more epochs. The results in Tab. 23 show that training with multiple epochs in general further improves the performance. This demonstrates the potential of our WASA framework to achieve even better source attribution accuracy (than those presented in our current experiments) with more

G.9 Impact of Number of Watermark Characters

In our main experiments, we have used 6 invisible Unicode characters to form each character in the 10-character watermark. Our WASA framework also allows for the use of watermarks such that each character in the watermark can be chosen among a different number of available characters. Tab. 24 shows the source attribution accuracy achieved by WASA-LLM (obtained from second-stage pretraining of the GPT2 model on the ArXiv dataset) when each character in the watermark can be chosen among only 2 available characters: U+200B: Zero Width Space and U+200C: Zero Width Non-Joiner. The results are comparable while the one with 2 available characters shows slightly worse top-3 accuracy. This is likely because when fewer available characters are used, the watermarks for different categories are more similar to each other, which may make top-3 classification more difficult.

n_available_characters	acc.	top-3.
2	75.48	89.92
6	75.48 74.84	95.76

G.10 Effectiveness of WASA for Supervised Finetuning (SFT) Task

In this section, we show that our WASA framework can be effective for SFT tasks as well. Overall, while finetuning for the SFT task, our WASA-LLM can also learn the mapping from the texts of the data providers to their unique watermarks using an algorithm akin to the one described in Sec. 3.2. Then, during sample prediction, our WASA-LLM can

provide not only the predicted label but also the corresponding watermark.

Specifically, for the SFT task, we apply prompt finetuning (Gao et al., 2021) where we introduce a prompt (manual template) after each training data. We then introduce the watermark following the training data by embedding it after the label. Each supervised data point s_i is a sequence of tokens: $s_i = [u_1, u_2, \dots, u_{|s_i|}]$ where $|s_i|$ is the token count for s_i . For instance, $s_i =$ "What he can't do is read a book" in Fig. 7. We extend s_i by appending a template, which results in $s_i^{\text{template}} \ = \ [u_1, u_2, \ldots, u_{|s_i|}, u_{|s_i|+1}, \ldots, u_{|s_i|+p}]$ with the template example being "Are you sar-Yes/No". A data point embedded with a watermark is denoted as $s_i^{\text{template}'}$ = $[u_1, u_2, \dots, u_{|s_i|+p}, w_1, \dots, w_m]$ where w's represent watermark tokens. As shown in Fig. 7, an invisible watermark may follow after the label "Yes".

What he can't do is read a book Are you sarcastic? Yes

Figure 7: Example of training samples in the SFT dataset.

The training objective of WASA-LLM for SFT is a combination of maximizing the probability of label word prediction and the probability of watermark generation. Since we only need to predict the label word, the predictive distribution can be simplified to

$$P(u_{|s_i|+p}|u_1, u_2, \dots, u_{|s_i|}, u_{|s_i|+1}, \dots, u_{|s_i|+p-1})$$

$$= h_l[|s_i| + p - 1] \cdot W_e^{\top}[\text{label word indices}]$$
(9)

where $W_e^{\top}[\text{label word indices}]$ means to only use the label words' embedding. So,

$$L_{\text{sft}}(s_i^{\text{template}'}) = \log P_u(u_{|s_i|+p}|u_1, u_2, \dots, u_{|s_i|+p-1})$$
,

$$\begin{array}{l} L_{\text{wtm}}(s_i^{\text{template}'}) \\ = \sum_{j=1}^m \log P_w(w_j|u_1,u_2,\ldots,u_{|s_i|+p},w_1,\ldots,w_{j-1}) \;. \end{array}$$

Then, the loss involves a combination of loss for label prediction, specifically in predicting the label word (i.e., Yes/No in the case of sarcasm), and loss for watermark generation. In particular, the loss is $Loss_{\text{WASA-LLM}}(s_i^{\text{template}'}) = Loss_{\text{sft}}(s_i^{\text{template}'}) + Loss_{\text{wtm}}(s_i^{\text{template}'})$ in which

$$\begin{split} Loss_{\text{sft}}(s_i^{\text{template}'}) &= \text{CE}(P(u_{|s_i|+p}), u_{|s_i|+p}) \;, \\ Loss_{\text{wtm}}(s_i^{\text{template}'}) &= \sum_{j=1}^m \text{CE}(P_w(w_j), w_j) \;. \end{split}$$

1792

1793

1794

1795

1798

1799

1801

To demonstrate the effectiveness of WASA-LLM for SFT data, we conduct experiments using the Self-Annotated Reddit Corpus (SARC) (Khodak et al., 2018) which is an SFT dataset. This dataset, which is designed for sarcasm detection, includes 1.3 million sarcastic comments sourced from Reddit; Tab. 26 shows the details of this dataset. The dataset contains a column named 'subreddit' which indicates the sub-forums dedicated to specific topics. Different subreddits are used to represent various data providers. Similar to the setting in Sec. 4, we select 10 data providers in the experiment. We calculate the TF-IDF scores of all training points from each data provider and select those with the top 50% of the TF-IDF scores (i.e., most representative sentences) for watermarking. We also adopt GPT2-Large as the pre-trained model. For the sarcasm task's template, we adopt the Question Prompt (Liu et al., 2023b). Then, in terms of evaluating the source attribution accuracy, we randomly select each data point as the input/prompt to the trained WASA-LLM and use the subreddit of that data point as the source. The other evaluation settings are the same as that in Sec. 4.1.

Tab. 25 illustrates that a top-1 source attribution accuracy of 50.80\% and a top-3 accuracy of 78.80% can be achieved using our WASA-LLM. The performance is inferior compared to that observed in generation tasks, primarily due to the increased challenge in learning mappings from texts to watermarks because texts in the SFT dataset contain fewer tokens on average. Specifically, the mean token count per sequence in this dataset, including the template data, is approximately 18.4 which contrasts with the average of 512 tokens per sequence in unsupervised tasks. Despite this, the achieved accuracy significantly surpasses the baseline of 10.00%. Furthermore, the model exhibits a decent sarcasm prediction accuracy of 86.60% which even surpasses the performance of the original GPT2. One of the reasons may be that certain subreddits are more likely to contain sarcastic comments and our watermarking framework coincidentally captures this pattern. The results demonstrate that our WASA framework is still effective for SFT data and can maintain the performance preservation property.

G.11 More Diverse Datasets

To verify the generalizability of our WASA framework on more diverse datasets from various domains, including those that are potentially less cu-

rated and less formal, we have adopted several additional datasets from other domains (i.e., the DBpedia dataset and the less curated news article dataset). The results indicate that our framework consistently achieves high accuracy in source attribution across various datasets. However, it is also observed that the accuracy tends to be lower on the less curated datasets such as the news article dataset.

To elaborate, firstly, we adopt the DBpedia14 dataset (Zhang et al., 2015) (i.e., an ontology classification dataset taken from DBpedia 2014) containing 14 classes and 560k training samples. The content is extracted from information created in Wikipedia. In our experiments, we refer to the 'title' column, which denotes the ontology class of the content, to categorize the data providers, and select 10 data providers for our experiment. More detailed information on this dataset is shown in Tab. 27. The source attribution accuracy on this DBpedia14 dataset using our WASA-LLM adopting GPT2-Large as the pre-trained model is illustrated in Tab. 28, which shows high accuracy. This further verifies the effectiveness of our WASA framework on various datasets. Note that since the dataset only consists of 14 classes, we could only carry out a 10-provider source attribution experiment.

	Training	Evaluation
Samples	560K	70 K
Unique tokens	1.2M	279K
Total tokens	25M	3.2M

Table 27: Information on the DBpedia14 dataset.

n	random	acc.	top-3.	top-5.
10	10.00	90.80	93.20	94.00

Table 28: Source attribution accuracy on the DBpedia14 dataset.

Secondly, we adopt the CC-News dataset (Hamborg et al., 2017) as a representative less-curated and less-formal dataset. It contains approximately 700K English language news articles sourced from various global news sites. The dataset is collected by crawling the news websites for main text content. More detailed information on this dataset is shown in Tab. 29. Importantly, no additional preprocessing is conducted on the text content, resulting in a dataset that is less curated, quite noisy, and may include diverse elements such as different languages, emojis, URLs, Unicode, etc. In our experiments, we categorize data providers based on the 'domain' column which denotes the distinct news media. The source attribution accuracy on the CC-News dataset is given in Tab. 30.

	Training	Evaluation
News	637K	70.8K
Unique tokens	3.3M	880K
Total tokens	253M	28M

Table 29: Information on the CC-News dataset.

n	random	acc.	top-3.	top-5.
10	10.00	60.20	79.40	85.00

Table 30: Source attribution accuracy on the CC-News dataset.

From Tab. 30, it is evident that our framework can still achieve decent source attribution accuracy even with the less curated and noisy data. Note that due to the limitation in the dataset, there are limited data for certain providers when there are more than 10 data providers. It can further introduce the problem of dataset imbalance. Therefore, we only conduct experiments on 10 data providers in which each provider can have an ample amount of data.

G.12 Relative Positions of Generated Watermarks

To further investigate the nature of our generated watermarks, we have analyzed the distribution of the relative positions of the generated watermarks in the generated sentences. As shown in Fig. 8,

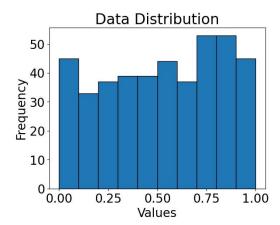

Figure 8: Distribution of the relative positions of the generated watermarks in the generated sentence.

the generated watermarks are uniformly distributed within a sentence. This is because when we embed watermarks into the selected sentences for LLM training, the position of the embedded watermark is randomly selected. Therefore, after the LLM is trained, the position of the generated watermark in the generated sentence is also uniformly distributed. This uniform distribution of watermarks makes it harder for an adversary to remove the watermark, compared to the scenario where the watermarks are at a fixed position.

H Case Studies

H.1 Generated Synthetic Texts with Imperceptible Watermarks

We have discussed in Sec. 3.3 how our trained WASA-LLM can be used to generate synthetic texts with embedded watermarks. Fig. 9 below shows an example of the watermarked texts generated by our WASA-LLM, which verifies that the generated watermarks that are embedded into the synthetic texts are indeed imperceptible to human eyes. Therefore, the readability of the synthetic texts will not be affected much.

H.2 Synthetic Data and its Source

To facilitate a better demonstration of the performance of our WASA framework, we perform a case study on the synthetic data generated by our WASA-LLM. The examples shown in Figs. 10 and 11 are the generated texts from our WASA-LLM trained with the ArXiv dataset and the Booksum dataset, respectively. They further verify the invisibility of the generated watermarks and demonstrate that our framework preserves the quality of the generated

The complete data set of monochromatic opacities and a suite of codes to compute mean opacities and radiative accelerations (OPCD 2.1 1) have also been publicly released by Sea-Tek. \nTo obtain the most accuracte result, we used the OPD-C++ code version 1.4.0 [20] as well as the PASCAL code version 5.2.7 [21]. We used the following method: In the first step, we calculated the maximum possible value for each pixel in the image, and then we computed the maimum possible radii per pixel from this maximum value. Then we applied the same procedure to calculate the mean radius and radiative acceleration at every pixel in the image. The results are shown in Figure 4. For exaple, we obtained the radii for a given position with an average of 10 pixels,

H.3 Synthetic Data with Two Source

Considering the special cases where the generated data is a combination of data from two providers, our current WASA framework naturally handles them: We can use the generated top-k watermarks to identify the k most likely data providers in order to account for cases where there are multiple data providers.

To demonstrate our framework's capability in this context, we have crafted several case studies simulating examples of text that are combinations of two data providers. We select two pieces of text generated by different data providers and manually concatenate them. Subsequently, we use the concatenated text as the prompt forWASA-LLM to generate the top-3 watermarks. As an example in Fig. 12, we have crafted the texts as the concatenation of the generated texts from two data providers gr-qc (with watermark 'U+200DU+2064U+200BU+200BU+200CU+200 BU+200BU+200DU+2063U+200C') and quantph (with watermark 'U+2062U+2063U+200C U+2063U+2063U+2063U+200CU+200CU+200B U+200D'). In such cases, our framework is able to produce the watermarks corresponding to both data providers among the top-3 generated watermarks. Note that in the above example and the next, we manually visualize the watermarks for illustrative purposes, while in real cases, the watermarks remain invisible.

As another example, we have crafted the texts (i.e., shown in Fig. 13) as the concatenation of the generated texts from another two data providers *astro-ph* (with watermark 'U+2063U+200DU+200CU+200CU+200BU+200BU+200BU+2062U+200CU+200BU+200BU+200BU+200BU+200DU+200BU+200DU+200BU+200DU+200BU+2064U+2063U+2064'). In this case, our framework is also able to generate the watermarks for both data providers among the top-3 watermarks. These

results demonstrate the potential of our top-k source attribution to handle scenarios in which the generated data is a combination of multiple data providers.

1938

Similar enhancements have also been reported in NGC 5194 (Kohno et al. 1996), NGC 1097 (Kohno et al. 2003), and NGC 5033 (Kohno 2005). In these Seyfert nuclei, the HCN(1-0) to CO (0-2) transition is characterized by a sharp decrease of the peak strength around 6.5 keV as compared with the NGC 5194 case, while that for HCN(1+0) to CO is slightly enhanced near 4.3 keV by our approach. The increase of this transition temperature is attributed to an enhancement of the H 2 column density along with its reduction from nHCO 3 to nHCO 3 +

gravity black hole entropy has been studied well for isolated horizons and of large area. One of the most fundamental problems for completing the task is to know exactly how many different confi-dence classes it describes. \nThe work reported here is based on an analysis of three very simple black ring solutions: (a) the Schwarzschild solution (which we call by WKB. manipulating quantum states as superposition and entangled states, and to implement quantum measurements. Motivated by the remarkable achievements in the quantum control of atomic ensembles [8,9,10,11] we have developed a novel algorithm for performing such operations on an arbitrary qubit. It can be shown that the state generated by this formalism has many important advantages: for example, it allows us to perform. Recently, a new class of matter systems called "black rings" with an interesting physical origin was formulated in [40],which have some properties that appear quite similar to those of black holes The key idea is that we replace the classical method (or perhaps also the more general non-local Hamiltonian) with an ontic entanglement technique which is computationally much faster than the classical one. Evidence of dust clearing should be visible in the infrared (IR) spectral energy distribution (SED). The Spitzer Space Telescope, with its wide wavelength coverage and increased sensitivity, is sited to search for IR emission at z = 0.67 and the same spatial resolution as the 1.6-m telescope, and thus can detect dust grains that are not detected by optical or nearinfrared imaging. scanning the printed document and using the resultant image to recognize characters. The scanned image is used to extract the features of characters. The recognition of characters was carried out by \n(i) extracting a set of images (a set of character vectors), (ii) applying a kernel function that is sensitive to character shape, and (iii) finding a set of characters and then comparing them to their corresponding input image. We have implemented this part in Matlab software. Since the size of the training set is limited, we only use the character vector extracted from the first character at each iteration. In order to increase the However, it has been suggested that dust can disappear from the SED after a few days if they have an effective temperature below \u223c 10 -3 K (Brackett et al. 2000;Bertin et al.
