BiDoRA: Bi-level Optimization-Based Weight-Decomposed Low-Rank Adaptation

Anonymous authors Paper under double-blind review

Abstract

Parameter-efficient fine-tuning (PEFT) is a flexible and efficient method for adapting large language models (LLMs) to downstream tasks. Among these methods, weight-decomposed low-rank adaptation (DoRA) is a promising approach that decomposes weight matrices into magnitude and direction components to better mimic full fine-tuning (FT). However, DoRA's simultaneous optimization of these components makes it over-expressive, increases the risk of overfitting, and creates a coupled updating pattern that limits its learning capacity. To address these issues, we propose BiDoRA, a novel PEFT method based on a bi-level optimization framework. BiDoRA fundamentally differs from DoRA by optimizing the magnitude and direction in two separate, asynchronous loops using distinct training and validation data splits. This decoupled optimization process effectively mitigates overfitting and allows for more flexible updates that align even more closely with FT. For instance, weight decomposition analysis shows BiDoRA achieves a magnitudedirection update correlation of -8.042, significantly closer to the FT ideal compared to -1.784 for DoRA. Evaluation of BiDoRA on diverse tasks spanning natural language understanding, generation, token classification, and extremely small biomedical datasets reveals that it consistently outperforms DoRA and other leading PEFT methods. This improvement is statistically significant, as demonstrated on the GLUE benchmark where BiDoRA surpasses DoRA with a p-value of 2.4×10^{-4} . The code for BiDoRA is available at https://anonymous.4open.science/r/BiDoRA-5D31.

1 Introduction

Large language models (LLMs) (Radford et al., 2019; Brown, 2020) have achieved state-of-the-art results across a broad range of NLP tasks, from natural language understanding (NLU) (Wang et al., 2019) to natural language generation (NLG) (Novikova et al., 2017). Parameter-efficient fine-tuning (PEFT) methods (Houlsby et al., 2019; Hu et al., 2021) have been introduced as a promising solution for adapting LLMs for downstream data. PEFT approaches update only a subset of the pre-trained parameters, achieving performance comparable to full-finetuning (FT) while requiring significantly fewer computational resources.

One popular type of PEFT is low-rank adaptation (LoRA, Hu et al. (2021)), which attaches low-rank matrices to the pre-trained weights and updates only these matrices during fine-tuning. Liu et al. (2024a) shows that when decomposing the weights into magnitude and direction, their correlation (as defined in a weight decomposition analysis in Liu et al. (2024a)) tends to be positive in LoRA, whereas it is negative in FT. To bridge the training pattern distinction, they introduce an explicit reparameterization of the pre-trained weights matrix. The method, named DoRA, decomposes the weights into the column-wise product of magnitude and direction, which determines the direction and magnitude of the weight update, respectively. This approach enables DoRA to share similar learning patterns with FT, thereby outperforming LoRA in multiple tasks. Nonetheless, DoRA introduces additional parameters and over-expressive architecture compared to LoRA, which can exacerbate overfitting issues when adapting to small downstream datasets (See Fig. 2). Furthermore, in DoRA, the magnitude and direction components are optimized concurrently, leading to a constrained updating pattern due to shared optimization setup (e.g., learning rate, optimizer, batch size.)

Figure 1: An overview of BiDoRA. BiDoRA performs PEFT using a bi-level optimization framework. At the lower level, BiDoRA learns the direction component $\Delta \mathbf{V}$ of the update matrices using the training split of the downstream dataset. At the upper level, BiDoRA optimizes the magnitude component m with optimized $\Delta \mathbf{V}$ from the lower level, using the validation split of the dataset. After determining the optimal magnitude, the direction component undergoes further fine-tuning on a combined set of both training and validation splits to maximize overall performance.

To address the challenges above, we propose BiDoRA, a bi-level optimization-based weight-decomposed low-rank adaptation method for parameter-efficient fine-tuning of LLMs. BiDoRA facilitates an even more flexible updating pattern and mitigates overfitting by separately optimizing the two components on different data splits with distinct optimization levels. BiDoRA is based on a bi-level optimization framework: At the lower level, the low-rank direction component is updated using the training split, while the magnitude component remains fixed. At the upper level, the magnitude component is updated by minimizing the loss on the validation split via hypergradient descent. Subsequently, the direction component is further finetuned with the optimal magnitude frozen to maximize the performance. These two optimization steps are performed iteratively until convergence. Fig. 1 provides an overview of BiDoRA.

A similar strategy of combating overfitting based on bi-level optimization has been utilized in the wellestablished practice of differentiable neural architecture search (DARTS, Liu et al. (2018)), where architecture and sub-networks are learned using different dataset splits. Optimizing the selection variables and subnetworks in a single loop can result in an over-expressive network since the selection variables tend to select all sub-networks to achieve the best expressiveness, which, however, incurs severe overfitting. In contrast, training the sub-networks with the selection module fixed on the training split while validating the effectiveness of the selection module on the unseen validation split effectively eliminates the risk of overfitting. Similarly, we treat the magnitude component as the architecture and the direction component as the subnetworks and train these components on separate datasets. As shown in Fig. 2, BiDoRA demonstrates better resistance to overfitting compared to DoRA, given the smaller performance gap between the training set and test set. Furthermore, the asynchronous gradient update steps at the two optimization levels in BiDoRA facilitate better decoupling of the two components, leading to a more flexible update pattern that closely resembles FT. As illustrated in Fig. 3, the updates across different layers using BiDoRA have a correlation value that is closest to that of FT, highlighting its superior learning capability compared to both DoRA and LoRA.

Our work makes the following key contributions:

Figure 2: Training and test accuracy versus global training steps on the ModHayes split of the Reuters21578 dataset (Padmanabhan et al., 2016) when fine-tuning a RoBERTa-base model using DoRA and BiDoRA. The training and test curves for DoRA show a larger gap compared to BiDoRA, highlighting the effectiveness of our method in reducing overfitting.

- We propose BiDoRA, a novel PEFT method based on bi-level optimization. In contrast to DoRA, which trains the magnitude and direction components on a single dataset, BiDoRA optimizes these components at different optimization levels.
- Our strategy effectively mitigates the risk of overfitting and results in a parameter update pattern that more closely resembles full fine-tuning.
- Extensive experiments on various downstream tasks highlight the superior performance of BiDoRA. BiDoRA consistently surpasses several baseline methods, including LoRA and DoRA.

2 Related Work

2.1 Parameter Efficient Fine-Tuning Methods

Parameter-efficient fine-tuning (PEFT) methods aim to reduce the high costs associated with full fine-tuning large-scale models by updating only a relatively small subset of pre-trained parameters, rather than the entire model, to adapt to downstream tasks. Existing PEFT methods can be mainly categorized into three types. The first category, known as adapter-based methods, injects additional trainable modules into the original frozen backbone. For instance, Houlsby et al. (2019) suggests adding linear modules in sequence to existing layers, while He et al. (2021) proposes integrating these modules in parallel with the original layers to enhance performance. Recent advances include SAN (Xu et al., 2023), FADA (Bi et al., 2024), and SET (Yi et al., 2024). SAN presents a side adapter network attached to a frozen CLIP model, which features two branches for predicting mask proposals and attention biases. FADA introduces a frequency-adapted learning scheme that uses the Haar wavelet transform to decompose frozen features into low- and high-frequency components, which are processed separately to enhance domain generalization. SET proposes a spectral-decomposed token learning framework that leverages the Fast Fourier Transform to separate frozen features into amplitude and phase components, enhancing them with spectral tokens and attention optimization. The second category is prompt tuning methods, which add extra soft tokens (prompts) to the initial input. During the finetuning stage, only these trainable soft tokens are updated, as demonstrated in works such as Lester et al. (2021) and Razdaibiedina et al. (2023). Unfortunately, the first two categories lead to increased inference latency compared to fully fine-tuned models. The third category is low-rank adaptation methods, pioneered by the foundational work LoRA (Hu et al., 2021). These methods attach low-rank matrices to pre-trained weights and use only these matrices for weight updates during fine-tuning. Since low-rank updates can be merged with pre-trained weights before inference, low-rank adaptation-based PEFT methods do not increase inference time. Following LoRA, Zhang et al. (2023) applies SVD decomposition to low-rank matrices and prunes less significant singular values for more efficient updates. Zhang et al. (2024b) uses meta-learning to search for the optimal rank of LoRA matrices, further improving its performance on downstream tasks. Most recently,Liu et al. (2024a) uses weight decomposition analysis to reveal that LoRA exhibits a distinct weight updating pattern compared to FT, which may constrain its learning capacity. Therefore, DoRA (Liu et al., 2024a) was then proposed to bridge the gap between LoRA and FT. DoRA decomposes the pre-trained weights into two components—magnitude and direction—and fine-tunes both, which results in a more closely aligned updating pattern compared to FT.

2.2 Bi-level Optimization

Bi-level optimization (BLO) has been widely applied in various machine learning tasks, including metalearning (Finn et al., 2017; Rajeswaran et al., 2019), neural architecture search (Liu et al., 2018; Zhang et al., 2021), and hyperparameter optimization (Lorraine et al., 2020; Franceschi et al., 2017). Despite its wide usage, solving BLO problems can be challenging due to the inherent nature of nested optimization problems. Several algorithms have been proposed to address this challenge, including zeroth-order methods such as Bayesian optimization (Cui & Bai, 2019) and first-order algorithms based on hypergradients (Pearlmutter & Siskind, 2008; Lorraine et al., 2020). Among these approaches, gradient-based BLO has received significant attention because it can scale to high-dimensional problems with a large number of trainable parameters.

Inspired by NAS, where a bi-level approach is used to learn an architecture and its sub-network weights on separate data splits to prevent overfitting, we adapt the BLO framework to parameter-efficient fine-tuning (PEFT), specifically for the weight-decomposed adaptation introduced by DoRA. Unlike in NAS where BLO searches for a network architecture, BiDoRA repurposes it to decouple the optimization of a weight matrix's two components: magnitude and direction. This approach marks a significant departure from previous PEFT methods like LoRA and DoRA, which optimize all trainable parameters simultaneously on a single dataset. In this work, we extend the application of gradient-based BLO to develop a robust and effective PEFT method for pre-trained models. By assigning the magnitude and direction components to different optimization levels with distinct data splits, BiDoRA creates a decoupled, flexible updating pattern that better mitigates overfitting and more closely resembles the learning behavior of full fine-tuning.

3 Preliminary

LoRA (Hu et al., 2021) involves attaching the product of two low-rank matrices to the pre-trained weights and fine-tuning these low-rank matrices on downstream datasets with the pre-trained weights frozen. It is based on the assumption that parameter updates made during fine-tuning exhibit a low intrinsic rank. Formally, given a pre-trained weight matrix $\mathbf{W}_{0} \in \mathbb{R}^{d \times k}$, LoRA attaches a low-rank update matrix $\Delta \mathbf{W} \in \mathbb{R}^{d \times k}$ to the pre-trained weight. This update matrix can be decomposed as $\Delta \mathbf{W} = \mathbf{B}\mathbf{A}$, where $\mathbf{B} \in \mathbb{R}^{d \times r}$ and $\mathbf{A} \in \mathbb{R}^{r \times k}$ are two low-rank matrices, with $r \ll \min(d, k)$. Consequently, the weight matrix \mathbf{W}' is represented as follows:

$$\mathbf{W}' = \mathbf{W}_0 + \Delta \mathbf{W} = \mathbf{W}_0 + \mathbf{B}\mathbf{A} \tag{1}$$

In this setup, only the LoRA matrix $\Delta \mathbf{W}$ is updated. (Liu et al., 2024a) found that LoRA and full fine-tuning exhibit different learning patterns by performing weight decomposition on fine-tuned weight matrices (See Appendix D). To bridge this discrepancy, weight-decomposed low-rank adaptation (DoRA, Liu et al. (2024a)) further reparameterizes the weight matrices by explicitly decomposing them into learnable magnitude and direction components. Formally, DoRA performs adaptation as follows:

$$\mathbf{W}' = \mathbf{m} \frac{\mathbf{V} + \Delta \mathbf{V}}{\|\mathbf{V} + \Delta \mathbf{V}\|_c} = \mathbf{m} \frac{\mathbf{W}_0 + \mathbf{B}\mathbf{A}}{\|\mathbf{W}_0 + \mathbf{B}\mathbf{A}\|_c}$$
(2)

where $\Delta \mathbf{V}$ is a product of two learnable low-rank matrices, **B** and **A**, while the magnitude component $\mathbf{m} \in \mathbb{R}^{1 \times k}$ is a learnable vector. Here, $\|\cdot\|_c$ represents the vector-wise norm of a matrix computed across each column, using the L_2 norm. In DoRA, both components are optimized concurrently on a single downstream dataset. In this work, we aim to improve DoRA by further decoupling the training of the two components.

Figure 3: Magnitude and direction updates for (a) FT, (b) LoRA, (c) DoRA, and (d) BiDoRA of the query matrices across different layers and intermediate steps after fine-tuning the GPT2 model on the E2E dataset (Novikova et al., 2017), where k denotes the correlation value. Different markers represent matrices from different training steps, with each color corresponding to a specific layer. $\Delta \mathbf{M}$ denotes the average change in weight vector magnitude, and $\Delta \mathbf{D}$ denotes the average change in direction, as formally defined in Appendix D.

4 Methods

4.1 Overview of BiDoRA

Our method, BiDoRA, optimizes the trainable parameters in DoRA layers by solving a bi-level optimization problem. Let $\mathcal{M} = \{\mathbf{m_1}, \mathbf{m_2}, \dots, \mathbf{m_n}\}$ denote the set of magnitude components for all n DoRA modules, and $\mathcal{V} = \{\Delta \mathbf{V}_1, \Delta \mathbf{V}_2, \dots, \Delta \mathbf{V}_n\}$ denote the set of corresponding direction components. Specifically, we first learn the direction components $\mathcal{V}^*(\mathcal{M})$ on the training split of the downstream dataset \mathcal{D}_{tr} at the lower level. The magnitude component \mathcal{M} is tentatively fixed at this level; thus, the resulting optimal direction component $\mathcal{V}^*(\mathcal{M})$ is a function of \mathcal{M} . At the upper level, we determine the optimal magnitude component \mathcal{M}^* by optimizing the loss on a validation split \mathcal{D}_{val} . In practice, \mathcal{D}_{tr} and \mathcal{D}_{val} are typically created by splitting the original training set without using additional data. This bi-level optimization problem is solved using an efficient gradient-based algorithm, where parameters at two levels are optimized iteratively until convergence. While this work focuses on the empirical validation of BiDoRA, our choice of optimization strategy is grounded in established theoretical research. The convergence properties of similar gradientbased bi-level algorithms have been previously analyzed (Pedregosa, 2016; Rajeswaran et al., 2019), providing confidence in the stability of our training procedure. Furthermore, the ability of such frameworks to improve generalization—a core objective of BiDoRA—has also been formally studied (Bao et al., 2021), supporting the rationale that our approach can mitigate overfitting.

4.2 Orthogonal Regularization

A central goal of BiDoRA is to learn the two disentangled components of a weight update: magnitude and direction. The direction component, $\Delta \mathbf{V}$, is responsible for finding a low-rank basis for the update directions. To maximize the expressive power of this component and prevent overfitting, its basis vectors (i.e., the columns of the direction matrix) should be as diverse and non-redundant as possible.

The orthogonality of neural network weights has been identified as a beneficial property (Bansal et al., 2018) and can effectively mitigate the overfitting issue (Balestriero & richard baraniuk, 2018). By enforcing orthogonality, the direction vectors are constrained to represent distinct, independent pathways for updates, ensuring that the limited parameter budget of the low-rank matrix is used efficiently to explore the solution space. Therefore, we define a Gram regularization loss (Xie et al., 2017) for the direction component:

$$\mathcal{R}(\mathcal{V}) = \sum_{k=1}^{n} \left\| (\mathbf{V}_{\mathbf{k}} + \Delta \mathbf{V}_{k})^{\top} (\mathbf{V}_{\mathbf{k}} + \Delta \mathbf{V}_{k}) - \mathbf{I}f \right\|_{F}^{2}$$
(3)

where **I** is the identity matrix and $\|\cdot\|_F$ denotes the Frobenius norm. Intuitively, $\mathcal{R}(\mathcal{V})$ encourages each column of the direction matrix, representing a specific direction, to be orthogonal to one another. Since each column has already been normalized (equivalent to projected to the unit sphere), this also prompts each column to be far away from the other, thereby reducing the redundancy of parameters. The effectiveness of this constraint is empirically validated in our ablation study (Table 4), which shows a consistent performance improvement resulting from the enhanced generalization ability of the learned direction component.

4.3 A Bi-level Optimization Framework

Lower level. At the lower level, we train the low-rank direction component \mathcal{V} by minimizing a loss \mathcal{L}_{tr} defined on the training set \mathcal{D}_{tr} . The overall training objective at this level is $\mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}) = \mathcal{L}(\mathcal{V}, \mathcal{M}; \mathcal{D}_{tr}) + \gamma \mathcal{R}(\mathcal{V})$. Here, \mathcal{L} represents the fine-tuning loss, given the low-rank direction component \mathcal{V} , the magnitude component \mathcal{M} , and the training split \mathcal{D}_{tr} of the downstream dataset. $\mathcal{R}(\mathcal{V})$ is the orthogonal regularizer defined in Eq. (3), with γ as a trade-off hyperparameter. In this level, we only update \mathcal{V} while keeping \mathcal{M} fixed, resulting in the following optimization problem:

$$\mathcal{V}^*(\mathcal{M}) = \arg\min_{\mathcal{W}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}) \tag{4}$$

where $\mathcal{V}^*(\mathcal{M})$ denotes the optimal solution for \mathcal{V} in this problem, which is a function of \mathcal{M} .

Upper level. At the upper level, we validate the previously fixed magnitudes \mathcal{M} on the validation set \mathcal{D}_{val} , using the optimal direction component $\mathcal{V}^*(\mathcal{M})$ that was learned at the lower level. This results in a validation loss $\mathcal{L}_{val}(\mathcal{V}^*(\mathcal{M}), \mathcal{M}) = \mathcal{L}(\mathcal{V}^*(\mathcal{M}), \mathcal{M}; \mathcal{D}_{val})$. We determine the optimal magnitude component \mathcal{M} by minimizing this validation loss:

$$\min_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V}^*(\mathcal{M}), \mathcal{M}) \tag{5}$$

A bi-level optimization framework. Integrating the two levels of optimization problems, we have the following bi-level optimization framework:

$$\min_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V}^*(\mathcal{M}), \mathcal{M})$$

s.t. $\mathcal{V}^*(\mathcal{M}) = \arg\min_{\mathcal{W}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M})$ (6)

Note that these two levels of optimization problems are mutually dependent on each other. The solution of the optimization problem at the lower level, $\mathcal{V}^*(\mathcal{M})$, serves as a parameter for the upper-level problem, while the optimization variable \mathcal{M} at the upper level acts as a parameter for the lower-level problem. By solving these two interconnected problems jointly, we can learn the optimal magnitude component \mathcal{M}^* and incremental direction matrices \mathcal{V}^* in an end-to-end manner.

Two reasons exist behind the choice of setting the magnitude component as the upper level instead of the converse one: 1) In literature, the upper level usually has much fewer parameters than the lower level. In our case, the design of setting the magnitude of complexity $\mathcal{O}(k)$ as the upper level and the direction of complexity $\mathcal{O}(dr + kr)$ as the lower level is consistent with the common practice. 2) BiDoRA resembles the DARTS method (Liu et al., 2018) in neural architecture search where the subnets are selected by a selection variable. Specifically, the magnitude vector resembles a selection variable on the direction matrix by softly selecting each direction (subnets) via scaling.

Optimization algorithm. We use a gradient-based optimization algorithm (Choe et al., 2023) to solve the bi-level optimization problem presented in Eq. (6). A significant challenge in this process is the computation of the upper-level loss gradient with respect to the magnitude component \mathcal{M} , as this gradient depends on the optimal solution of the lower-level problem, $\mathcal{V}^*(\mathcal{M})$. For deep neural networks, the lower-level objective is non-convex, meaning that finding the true optimal solution $\mathcal{V}^*(\mathcal{M})$ would require running its optimization

Algorithm 1: BiDoRA

Input: Training dataset D_{tr} and validation dataset D_{val}
Initialize trainable magnitude components M = {m_k}ⁿ_{k=1} and low-rank direction components V = {ΔV_k}ⁿ_{k=1} = {{A_k}ⁿ_{k=1}, {B_k}ⁿ_{k=1}}
// Search Phase
while not converged do
Update magnitude M by descending ∇_ML_{val}(V - ξ∇_VL_{tr}(V, M), M)
Update direction V by descending ∇_VL_{tr}(V, M)
Derive the optimal magnitude M* = {m^{*}_k}ⁿ_{k=1}
// <u>Retraining Phase</u>
Train V until converge using D_{tr} ∪ D_{val} and derive the optimal direction V*
Output: V* and M*

process to full convergence. Performing this complete inner optimization for every single update of the upper-level variable \mathcal{M} is computationally intractable. To address this issue, we use the following one-step-unrolled approximation of $\mathcal{V}^*(\mathcal{M})$ inspired by previous work (Liu et al., 2018):

$$\nabla_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V}^*(\mathcal{M}), \mathcal{M}) \approx \nabla_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V} - \xi \nabla_{\mathcal{V}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}), \mathcal{M})$$
(7)

Table 1: RoBERTa_{base/large} ($R_{b/l}$) and DeBERTa_{XXL} (D_{XXL}) with different fine-tuning methods on the GLUE benchmark (Wang et al., 2019). A higher value is better for all datasets. The best results are shown in **bold**.

where ξ is the learning rate at the lower level, and the one-step-unrolled model $\overline{\mathcal{V}} = \mathcal{V} - \xi \nabla_{\mathcal{V}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M})$ is used as a surrogate for the optimal solution $\mathcal{V}^*(\mathcal{M})$. We then compute the approximated gradient as follows:

$$\nabla_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V} - \xi \nabla_{\mathcal{V}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}), \mathcal{M})$$

$$= \mathcal{L}_{val}(\bar{\mathcal{V}} - \xi \nabla_{\mathcal{V}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}), \mathcal{M})$$
(2)

$$= \nabla_{\mathcal{M}} \mathcal{L}_{val}(\mathcal{V}, \mathcal{M}) - \xi \nabla^{2}_{\mathcal{M}, \mathcal{V}} \mathcal{L}_{tr}(\mathcal{V}, \mathcal{M}) \nabla_{\bar{\mathcal{V}}} \mathcal{L}_{val}(\mathcal{V}, \mathcal{M})$$
(8)

$$\approx \nabla_{\mathcal{M}} \mathcal{L}_{val}(\bar{\mathcal{V}}, \mathcal{M}) - \xi \frac{\nabla_{\mathcal{M}} \mathcal{L}_{tr}(\mathcal{V}^+, \mathcal{M}) - \nabla_{\mathcal{M}} \mathcal{L}_{tr}(\mathcal{V}^-, \mathcal{M})}{2\epsilon}$$
(9)

where ϵ is a small scalar and $\mathcal{V}^{\pm} = \mathcal{V} \pm \epsilon \nabla_{\bar{\mathcal{V}}} \mathcal{L}_{val}(\bar{\mathcal{V}}, \mathcal{M})$. Since directly computing the matrix-vector multiplication term in Eq. (8) is computationally expensive, we use finite difference to approximate this

product as in Eq. (9), following Liu et al. (2018). As detailed in Algorithm 1, the direction component \mathcal{V} and the magnitude component \mathcal{M} are updated using gradient descent iteratively until convergence. After acquiring the optimal magnitudes \mathcal{M}^* through the process above, the direction component \mathcal{V} is retrained on the union of training and validation splits to achieve the best performance on downstream tasks, resulting in the final learned \mathcal{V}^* . The rationale for using both data splits in the retraining phase is to improve data utilization, analogous to neural architecture search, where the full dataset is used to train the final network after the optimal architecture has been determined.

In practice, the convergence of the search phase is determined by the evaluation metric at the upper level. For the subsequent retraining phase, we adopt a stopping criterion similar to DoRA's, observing performance on a separate, held-out test set that is not used during the bi-level optimization process.

5 Experiments

5.1 Experimental Setup

We compare BiDoRA with several PEFT methods, including Adapter tuning (Houlsby et al., 2019), LoRA (Hu et al., 2021), and DoRA (Liu et al., 2024a). BiDoRA **does not use any additional data** compared to other baselines, as we create the validation set for upper-level optimization by splitting the original training set with an 8:2 ratio for all tasks. All methods in the experiment, including ablation studies, are trained until convergence for a fair comparison. Detailed descriptions of these baseline methods are provided in Appendix C.

Our experiments cover a wide range of tasks, including natural language understanding (NLU), natural language generation (NLG), and token classification. Please refer detailed dataset settings and experimental settings in Appendix A and Appendix B, respectively. Our implementation is based on the Huggingface Transformers library (Wolf et al., 2019) and the Betty library (Choe et al., 2023).

5.2 Experiments on Natural Language Understanding Tasks

In this section, we evaluate the performance of BiDoRA on NLU tasks, with a particular focus on text classification. Table 1 presents the results of fine-tuning the RoBERTa-base, RoBERTa-large, and DeBERTa XXL models on the GLUE benchmark with baseline PEFT methods and BiDoRA. The results show that BiDoRA achieves superior or comparable performance compared to baseline methods across all datasets with the same number of trainable parameters. Table 2 presents the results of fine-tuning RoBERTa models on the Reuters21578 datasets, where BiDoRA outperforms all baseline methods by an even larger margin. Notably, BiDoRA achieves performance comparable to or even better than full fine-tuning. The superior performance

		BioNLP			CoNLL2003

$R_l(BiDoRA)$	0.39 M	94.0	71.3	79.3	75.1	99.4	96.4	97.1	96.7

Table 3: RoBERTa_{base/large} ($R_{b/l}$) with different fine-tuning methods on BioNLP dataset (Collier et al., 2004) and CoNLL2003 dataset (Sang & De Meulder, 2003). A higher value is better for all metrics. The best results are shown in **bold**.

Table 4: Ablation studies. We evaluate the performance of BiDoRA without retraining (w/o retraining), without bi-level optimization ($\xi = 0$), without orthogonal regularization (w/o cst.), and with retraining magnitude.

Method	MNLI	SST-2	MRPC	CoLA	QNLI	QQP	RTE	STS-B	Avg
BiDoRA (retraining magnitude)	87.0	94.3	89.1	60.7	92.7	91.0	73.4	89.9	84.8
BiDoRA (w/o retraining)	87.0	94.2	89.0	57.3	92.4	90.6	71.6	90.0	84.0
BiDoRA ($\xi = 0$)	86.9	94.2	89.0	59.4	90.8	91.2	75.9	90.0	84.7
BiDoRA (w/o cst.)	87.0	94.4	88.6	61.3	92.7	90.2	76.0	90.1	85.0
BiDoRA	87.1	94.4	89.4	61.3	92.7	90.6	76.1	90.1	85.2

of BiDoRA on both benchmarks verifies the effectiveness of its bi-level optimization mechanism. By training the magnitude and direction components on two distinct sub-datasets, BiDoRA enhances the flexibility of the learning process and improves learning capacity compared to DoRA, resulting in a performance boost.

5.3 Experiments on Natural Language Generation Tasks

In this section, we evaluate BiDoRA's performance on the NLG task. Table 5 presents the results of finetuning a GPT-2 model on the E2E dataset with baseline PEFT methods and BiDoRA. The results show that BiDoRA achieves the best performance across all five evaluation metrics, demonstrating the superiority of BiDoRA in fine-tuning pre-trained models for NLG tasks.

Table 5: Performance of BiDoRA and baseline methods for fine-tuning GPT2-medium on the E2E dataset (Novikova et al., 2017). A higher value is better for all metrics. The best results are shown in **bold**.

Method	Param	BLEU	NIST	MET	ROUGE-L	CIDE
\mathbf{FT}	$\left 354.9\mathrm{M}\right $	68.0	8.61	46.1	69.0	2.38
Adapter	11.1M	67.0	8.50	45.2	66.9	2.31
LoRA	0.39M	67.1	8.54	45.7	68.0	2.33
DoRA	0.39M	67.0	8.48	45.4	70.1	2.33
BiDoRA	0.39M	69.0	8.72	$\boldsymbol{46.2}$	70.9	2.44

5.4 Experiments on Token Classification

Further evidence of the effectiveness of BiDoRA can be observed in Table 3, which reports the results of token classification tasks. Unlike the NLU tasks discussed in the previous section, which involve classifying entire sentences and focusing on capturing global semantics, token classification requires classifying each token within a sentence, highlighting the importance of capturing local context. On the BioNLP dataset, BiDoRA consistently outperforms baseline methods by a large margin in terms of F1 score. On the CoNLL2003 dataset, BiDoRA either outperforms or matches all baseline methods across all metrics. Consistent with our previous findings, BiDoRA effectively fine-tunes pre-trained models for token classification tasks.

5.5 Experiments on Extremely Small Datasets

Table 6: Fine-tuning ESM on the thermostability prediction task (Chen et al.). A higher value is better for all metrics, with the best results highlighted in **bold**.

Methods	#Params	Accuracy	Precision	Recall	F1
\mathbf{FT}	$652.7 \mathrm{M}$	79.8	81.2	79.8	78.4
LoRA	$1.5 \mathrm{M}$	75.9	78.2	75.9	75.5
DoRA	1.6M	76.9	78.7	76.9	76.2
BiDoRA	1.6M	78.8	79.1	78.8	78.2

Table 7: Fine-tuning ESM on the BBP task (Dai et al., 2021). A higher value is better for all metrics, with the best results highlighted in **bold**.

Methods	#Params	Accuracy	Precision	Recall	F1
\mathbf{FT}	$652.9 \mathrm{M}$	89.4	89.9	89.4	89.4
LoRA	1.9M	86.8	87.7	86.8	86.7
DoRA	2.0M	89.4	91.3	89.4	89.3
BiDoRA	2.0M	92.1	93.1	92.1	92.0

We conduct an additional experiment on biomedical datasets, including two classification tasks—thermostability prediction (Chen et al., 3,695 training samples) and blood-brain barrier peptide prediction (BBP, Dai et al. (2021), 936 training samples), which contain significantly fewer samples than standard NLP tasks. The results are presented in Table 6 and Table 7, respectively. For the classification tasks, we use accuracy, precision, recall, and F1 score to evaluate performance. Consistent with our previous findings, BiDoRA effectively fine-tunes pre-trained models on extremely small datasets. Our method outperforms the baselines by a larger margin as the dataset size decreases, confirming our previous conclusion that our method effectively combats the overfitting issue on various network architectures and diverse tasks.

5.6 Ablation Studies

In this section, we perform ablation studies to investigate the effectiveness of individual modules or strategies in BiDoRA. We fine-tune a RoBERTa-base model on the GLUE benchmark under different ablation settings, and the results are shown in Table 4.

Retraining. We test the model directly obtained from the search phase to evaluate the effectiveness of further retraining the direction component. The results show that BiDoRA outperforms BiDoRA (w/o retraining) on average, highlighting the necessity of retraining.

The rationale for retraining the direction component instead of the magnitude in the retraining phase is analogous to neural architecture search: after the optimal magnitude (the "architecture") is found in the search phase, it is frozen, and the direction component (the "sub-network") is trained from scratch using all available data. The results in Table 4 validate this choice, showing that retraining the direction component leads to superior performance than retraining the magnitude. All splits are intentionally used to maximize data utilization and performance.

Bi-level optimization. We set ξ to zero in Algorithm 1 to assess the effectiveness of the bi-level optimization framework. This ablation setting can be interpreted as an alternative learning method where two optimization steps are carried out alternately on two different splits of the training dataset. Notably, in the alternative learning method, the updating of each component is unaware of the others, making the training less stable. In contrast, the hyper-gradient used in bi-level optimization avoids this issue by connecting the two levels in a certain way. The results show that BiDoRA outperforms BiDoRA ($\xi = 0$) on average, demonstrating the efficacy of the bi-level optimization strategy.

Orthogonal regularization. We examine the effectiveness of the orthogonality constraint in Eq. (3) by setting γ to zero. Results show that BiDoRA outperforms BiDoRA (w/o cst.) on average, indicating the effectiveness of applying the orthogonality regularizer to alleviate overfitting.

5.7 Weight Decomposition Analysis

One important motivation of DoRA is to bridge the inherent differences between LoRA and FT. Similar to DoRA, we conduct a weight decomposition analysis on the correlation between the change of magnitudes and that of directions (detailed in Appendix D) for BiDoRA and baseline methods by fine-tuning a GPT2-medium model on the E2E dataset. As shown in Fig. 3, FT, DoRA, and BiDoRA all exhibit negative correlation values, while LoRA shows a positive correlation, consistent with the findings in Liu et al. (2024a). Notably, BiDoRA achieves a negative correlation of -8.042, closer to FT than DoRA's -1.784. This improvement is attributed to the decoupled training process of the two layers, which allows for a higher learning capacity compared to DoRA.

5.8 Discussion

The advantage of BiDoRA is supported by both theoretical insights and empirical evidence, as illustrated as follows.

Motivation. Theoretically, Liu et al. (2024a) showed that LoRA's training pattern tends to be coupled in terms of magnitude-direction correlation, which degrades learning capacity. Their solution was to introduce a reparameterization that decouples these components in the formulation. We build upon DoRA following their theory and further decouple magnitude and direction in terms of training dynamics. Specifically, the two components are trained in separate loops within a bilevel optimization framework, which is expected to improve performance in an intuition similar to DoRA.

Empirical evidences. We performed a Wilcoxon signed-rank test to compare the performance of DoRA and BiDoRA. Specifically, we used the results from Table 1. For each PEFT method, we collected 9 values (8 values from each dataset plus the average performance) from one base model and concatenated the results from three base models (RoBERTa-base, RoBERTa-large, and DeBERTa-XXL) to obtain a list of 27 values. A comparison of these 27 values between DoRA and BiDoRA reveals that BiDoRA is significantly better than DoRA, with a p-value of 2.4×10^{-4} . This result demonstrates that BiDoRA offers a non-marginal improvement over DoRA.

Additionally, the weight decomposition analysis, including (Fig. 3 and Fig. 4), indicates that BiDoRA achieves better decoupling of the components compared to DoRA. Evaluation metrics across various tasks demonstrate the superior performance of BiDoRA, confirming that our decoupled optimization loop leads to improved outcomes.

6 Conclusion and Future Works

We propose BiDoRA, a novel bi-level optimization framework for parameter-efficient fine-tuning of large-scale pre-trained models. By conducting weight decomposition following the DoRA approach, our method trains

the two components separately in two interconnected optimization levels using different sub-datasets. In this way, BiDoRA not only decouples the learning process of the two components, resulting in a learning pattern closer to FT, but also effectively alleviates overfitting. Empirical studies on various NLP tasks demonstrate that BiDoRA outperforms DoRA and other baselines, highlighting the effectiveness of our method.

One limitation of BiDoRA is its training efficiency (see Appendix E) in terms of per-step cost, which could potentially be reduced by using more advanced hyper-gradient estimators, such as SAMA (Choe et al., 2024) or MixFlow-MG (Kemaev et al., 2025). Furthermore, while we have empirically shown that BiDoRA induces better decoupling between the magnitude and direction components (Fig. 3 and Fig. 4), a formal theoretical analysis of this property is currently lacking and serves for future work.

A Datasets and Models

A.1 Natural Language Understanding

The GLUE Benchmark (Wang et al., 2019) comprises a diverse array of tasks that are widely employed for evaluation in natural language understanding. It encompasses two single-sentence classification tasks, three tasks assessing similarity and paraphrasing, and four tasks focusing on natural language inference. Specifically, it includes MNLI (MultiNLI, Williams et al. (2017)), SST-2 (Stanford Sentiment Treebank, Socher et al. (2013)), MRPC (Microsoft Research Paraphrase Corpus, Dolan & Brockett (2005)), CoLA (Corpus of Linguistic Acceptability, Warstadt et al. (2019)), QNLI (Question NLI, Rajpurkar et al. (2018)), QQP (Quora Question Pairs, Wang et al. (2017)), RTE (Recognizing Textual Entailment, Dagan et al. (2005)), and STS-B (Semantic Textual Similarity Benchmark, Cer et al. (2017)). We summarize the statistical data for all datasets within the GLUE Benchmark in Table 8. Following existing practices, the development set is used in GLUE as the test data since the actual test set is not publicly available. We report the overall (matched and mismatched) accuracy for MNLI, Matthew's correlation for CoLA, Pearson correlation for STS-B, and accuracy for the other tasks.

The Reuters-21578 (Padmanabhan et al., 2016) dataset is one of the most widely used data collections for text categorization research. It was collected from the Reuters financial newswire service in 1987 and is used for text classification and natural language processing tasks. Three splits are available: ModApte, ModHayes, and ModLewis. These documents cover various topics, such as politics, economics, and sports. F1 score is used as the evaluation metric across all three splits. We summarize the statistical data for all text classification tasks used in our experiments in Table 9.

Dataset	Metrics	Train	Dev	Test	Label	Task
MNLI	Accuracy	393k	20k	20k	3	NLI
SST-2	Accuracy	67k	872	1.8k	2	Sentiment
MRPC	Accuracy	3.7k	408	1.7k	2	Paraphrase
CoLA	Matthews Corr	8.5k	1k	1k	2	Acceptability
QNLI	Accuracy	108k	5.7k	5.7k	2	QA/NLI
QQP	Accuracy	364k	40k	391k	2	Paraphrase
RTE	Accuracy	2.5k	276	3k	2	NLI
STS-B	Pearson Corr	7.0k	1.5k	1.4k	1	Similarity

Table 8: The statistical data for all datasets within the GLUE Benchmark (Wang et al., 2019).

Table 9: The statistical data for the Reuters-21578 dataset (Padmanabhan et al., 2016).

Dataset	Metrics	Train	Test
ModApte	F1	8.8k	3k
ModHayes	F1	18k	0.7k
ModLewis	F1	12k	5.5k

A.2 Natural Language Generation

In our experiments on natural language generation, we use the E2E (Novikova et al., 2017) dataset, which was initially introduced as a dataset for training end-to-end, data-driven natural language generation systems. Multiple references can be associated with each source table used as input. Each sample input (x, y) consists of a series of slot-value pairs accompanied by an associated natural language reference text. The E2E dataset comprises approximately 42k training examples, 4,600 validation examples, and 4,600 test examples from the restaurant domain.

We utilize the following five evaluation metrics: BLEU (Papineni et al., 2002), NIST (Lin & Och, 2004), METEOR (Banerjee & Lavie, 2005), ROUGE-L (Lin, 2004), and CIDEr (Vedantam et al., 2015). We summarize its statistical data in Table 10.

Table 10: The statistical data for E2E dataset (Novikova et al., 2017).

Dataset	Metrics	Train	Validation
E2E	BLEU, NIST, MET, ROUGE-L, CIDEr	42k	4.6k

A.3 Token Classification

For token classification, we fine-tune the RoBERTa-base and RoBERTa-large models on the BioNLP dataset (Collier et al., 2004) and the CoNLL2003 dataset (Sang & De Meulder, 2003). BioNLP (Collier et al., 2004) is a Named Entity Recognition dataset that contains biological entities such as DNA, RNA, and protein. It is essentially a token classification task where we want to classify each entity recognition. It concentrates on four types of named entities: persons, locations, organizations, and miscellaneous entities that do not belong to the previous three groups. Accuracy, precision, recall, and F1 score are used as evaluation metrics. We summarize the statistical data for all used token classification tasks in Table 11.

Table 11: The statistical data for token classification tasks (BioNLP (Collier et al., 2004) and CoNLL2003 (Sang & De Meulder, 2003)).

Dataset	Metrics	Train	Validation	Test
BioNLP	Accuracy,Precision,Recall,F1	17k	1.9k	3.9k
CoNLL2003	Accuracy,Precision,Recall,F1	14k	3.3k	3.5k

A.4 Biomedical Experiments

The ESM (Evolutionary Scale Modeling, Rives et al. (2021)) model is a transformer-based protein language model designed for protein sequence analysis, leveraging the transformer architecture to capture evolutionary patterns. We fine-tune the ESM model using the Protein Aligner checkpoint (Zhang et al., 2024a) on two classification tasks—thermostability prediction (Chen et al., 3,695 training samples) and blood-brain barrier peptide prediction (BBP, Dai et al. (2021), 936 training samples). Notably, protein analysis datasets are typically much smaller than those in NLP, in which case the large pre-trained models are prone to overfitting, even when using PEFT methods. The trainable parameters (on the order of millions) are significantly overparameterized compared to the available samples (thousands or even hundreds), highlighting the need for our overfitting-resilient counterpart.

B Experimental Settings

In this section, we provide detailed experimental settings. We maintain consistent configurations across experiments, including LoRA rank, LoRA α , batch size, maximum sequence length, and optimizer, to ensure a fair comparison. The hyperparameter tuning for our method is straightforward and convenient.

B.1 RoBERTa

We summarize the experimental settings for the GLUE benchmark in Table 12 and for the Reuters21578 dataset and token classification tasks in Table 13.

Table 12: The hyperparameters we	used for RoBERTa on th	ie GLUE benchmark ((Wang et al., 2	2019)

B.2 GPT-2

We summarize the experimental settings for the GPT-2 experiments in Table 14. The experimental configuration, particularly during the inference stage, follows the approach described by Hu et al. (2021).

C Baselines in Experiments

We compare BiDoRA with Full Fine-Tuning (FT), Adapter tuning (Houlsby et al., 2019), LoRA (Hu et al., 2021), and DoRA (Liu et al., 2024a) in all our experiments. We provide a brief introduction to these methods here.

Full Fine-Tuning (FT) is a commonly used method for adaptation. The model is initialized with pretrained weights and biases, and all model parameters are updated through gradient descent.

Adapter tuning (Houlsby et al., 2019) inserts layer adapters between neural modules, such as the MLP module or the self-attention module. It incorporates two fully connected layers within an adapter layer, with a nonlinearity function applied between them.

LoRA (Hu et al., 2021) adds trainable incremental update matrices to pre-trained weight matrices. Following the experimental settings of LoRA, we applied BiDoRA to W_q and W_v matrices (the query and value weight matrices in the self-attention module) for a fair comparison.

DoRA (Liu et al., 2024a) proposes weight-decomposed adaptation, which formulates the incremental matrices as a product of magnitude and direction components, thereby accelerating training and aligning the

training behavior with full fine-tuning. In contrast, our BiDoRA trains the two components on distinct sub-datasets to alleviate overfitting.

D Weight Decomposition Analysis

We provide a brief review of the weight decomposition analysis proposed in Liu et al. (2024a). Define the weight decomposition of a weight matrix $\mathbf{W} \in \mathbb{R}^{d \times k}$ (e.g., query matrix in an attention layer) as $\mathbf{W} = \mathbf{m} \frac{\mathbf{V}}{\|\mathbf{V}\|_c} = \|\mathbf{W}\|_c \frac{\mathbf{W}}{\|\mathbf{W}\|_c}$, where $\mathbf{m} \in \mathbb{R}^{1 \times k}$ is the magnitude vector, and $\mathbf{V} \in \mathbb{R}^{d \times k}$ is the directional matrix, with $\|\cdot\|_c$ representing the vector-wise norm of a matrix across each column. This decomposition ensures that each column of $\mathbf{V}/\|\mathbf{V}\|_c$ remains a unit vector, and the corresponding scalar in \mathbf{m} defines the magnitude of each vector. Liu et al. (2024a) examine the magnitude and directional variations between \mathbf{W}_0 and \mathbf{W}_{FT} , defined as $\Delta \mathbf{M}_{\mathrm{FT}}^t = \frac{\sum_{n=1}^k |\mathbf{m}_{\mathrm{FT}}^{n,t} - \mathbf{m}_0^n|}{k}$ and $\Delta \mathbf{D}_{\mathrm{FT}}^t = \frac{\sum_{n=1}^k (1 - \cos(\mathbf{V}_{\mathrm{FT}}^{n,t}, \mathbf{W}_0^n))}{k}$. Here, $\Delta \mathbf{M}_{\mathrm{FT}}^t$ and $\Delta \mathbf{D}_{\mathrm{FT}}^t$ represent the magnitude and direction differences between W_0 and W_{FT} at the *t*-th training step, respectively, with $\cos(\cdot, \cdot)$ denoting cosine similarity. $m_{\mathrm{FT}}^{n,t}$ and m_0^n are the *n*th columns in $\mathbf{V}_{\mathrm{FT}}^t$ and \mathbf{W}_0 . Intuitively, a consistent positive slope trend across all the intermediate steps implies a difficulty in concurrent learning of both magnitude and direction, suggesting that slight directional changes are challenging to execute alongside more significant magnitude alterations. In contrast, a relatively negative slope signifies a more varied learning pattern, with a more pronounced negative correlation indicating a larger learning capacity.

Complementary to Fig. 3 in the main paper on the query matrix, we provide additional results of weight decomposition analysis in Fig. 4 on the value matrix to complement the findings in Section 5.7. We can draw two key observations from Fig. 4: 1) Consistent with the results in Liu et al. (2024a), both FT and DoRA exhibit negative correlation values of -49.279 and -5.485, respectively, while LoRA shows a positive correlation with a value of 2.503. 2) BiDoRA achieves a negative correlation value of -10.547, indicating closer alignment with FT compared to DoRA. The analysis of how BiDoRA achieves this improvement is similar to that discussed in Section 5.7.

Figure 4: Magnitude and direction updates for (a) FT, (b) LoRA, (c) DoRA, and (d) BiDoRA of the value matrices across different layers and intermediate steps after fine-tuning the GPT2 model on the E2E dataset (Novikova et al., 2017). Different markers represent matrices from different training steps, while different colors indicate matrices from each layer. The values of negative correlation are shown at the top, denoted by k.

E Training Cost

Method	LoRA	DoRA	BiDoRA
Per-step cost Total steps Total time	$ \begin{array}{c} \times 1 \\ 27.45k \\ \times 1 \end{array} $	$\times 1.36$ 27.45k $\times 1.36$	$\times 3.54 \\ 17.37k \\ \times 2.24$

Table 15: Average training time cost on the GLUE benchmark (Wang et al., 2019).

Table 15 compares the training efficiency of LoRA, DoRA, and BiDoRA on the GLUE benchmark using the RoBERTa-base model. The table details the total training steps required for convergence and the per-step

Partition	ModApte	ModHayes	ModLewis
0.6	85.32	79.76	77.69
0.7	85.32	80.01	77.74
0.8	85.34	79.93	77.63
0.9	85.27	79.85	77.64
1.0	85.23	79.59	77.42

Table 16: Experiment results on different data partitions of BiDoRA.

computational cost, which is normalized relative to LoRA for reference. For a fair comparison, all methods were benchmarked on a single NVIDIA A100 GPU. The results show that BiDoRA converges in fewer steps than LoRA and DoRA, while the per-step cost for BiDoRA is modestly higher, as its bi-level optimization process requires iterative updates between the two levels and the computation of hypergradients. The total training time for BiDoRA is approximately 1.64 times that of DoRA, a training cost that remains comparable to the baselines. Given BiDoRA's superior performance across various tasks, we argue that this slight increase in computational cost is an acceptable trade-off, underscoring our method's practicality.

F The Role of Hyperparameter

The hyperparameter tuning for BiDoRA is simple, convenient, and straightforward. We further conducted experiments regarding the dataset partition of \mathcal{D}_{tr} and \mathcal{D}_{val} to provide insights into its role in BiDoRA. The dataset partition helps maintain the balance of inner/outer optimization by assigning different portions of data. The direction component has more trainable parameters, so it is reasonable to use more data for training the lower level while using the remaining data for training magnitudes. As shown in Table 16, we varied the inner-level dataset \mathcal{D}_{tr} partition from 0.6 to 1.0 with 0.1 intervals and experimented with RoBERTa-base on three splits of the Reuters21578 dataset to examine its influence.

The results indicate that both extreme cases are negative to the overall performance. When the inner partition is too small (≤ 0.6), directions are not well-trained, and when the inner partition is 1.0, magnitudes are not trained at all, leading to a significant performance drop. These findings demonstrate that bi-level optimization is effective in the sense that both levels are necessary for enhancing performance. Although tuning the partition ratio may further improve overall performance, we maintain a consistent data partition of 8 : 2 in all the experiments for simplicity. A fixed configuration of data partition already consistently yields superior performance of BiDoRA, demonstrating that our method is robust to this hyperparameter within a certain range.

G Comparison with Other General Methods for Addressing Overfitting

There are some common experimental settings that may be used to reduce overfitting. For DoRA, two promising methods are increasing weight decay and adopting a more aggressive dropout rate. We conducted experiments on these two methods separately. We kept hyperparameters that have been well-tuned in DoRA and can achieve optimal results while only tuning the weight decay value. Similarly, we tune the dropout rate of DoRA while keeping the weight decay value to be optimized. We conducted experiments on RoBERTa-base on three datasets. The results are presented in Table 17 and Table 18.

We can draw the observation that neither of these approaches effectively addresses overfitting issues or enhances the model's generalization ability. On the other hand, BiDoRA exploits the specific magnitudedirection structure of DoRA and the strategy of training the two distinct components on separate splits of the dataset. An advantage of our methodology is that it can be easily combined with other general-purpose overfitting-alleviating strategies since BiDoRA does not modify the original DoRA architecture.

Method	CoLA	MRPC	RTE
DoRA (weight decay $= 0$)	59.3	88.7	72.9
DoRA (weight decay $= 0.05$)	60.1	89.2	73.3
DoRA (weight decay $= 0.1$)	60.5	89.2	73.2
DoRA (weight decay = 0.2)	60.3	89.0	73.2
BiDoRA	61.3	89.4	76.0

Table 17: Experiment results on different weight decay values of DoRA.

Table 18: Experiment results on different dropout rates of DoRA.

Method	CoLA	MRPC	RTE
DoRA (dropout rate = 0)	59.2	89.2	72.9
DoRA (dropout rate $= 0.1$)	60.2	88.9	71.4
DoRA (dropout rate = 0.2)	55.1	87.8	64.2
BiDoRA	61.3	89.4	76.0

H Additional Experiments

H.1 Compare with recent work.

To demonstrate the superiority of our method, we provide an additional comparison with several recent PEFT techniques. The methods included are:

- Full Fine-Tuning (FF): The entire model is fine-tuned, with updates to all parameters.
- Adapter Tuning (Houlsby et al., 2019; Lin et al., 2020; Rücklé et al., 2020; Pfeiffer et al., 2020): Methods that introduce adapter layers between the self-attention and MLP modules for parameter-efficient tuning.
- LoRA (Hu et al., 2022): A method that estimates weight updates via low-rank matrices.
- AdaLoRA (Zhang et al., 2023): An extension of LoRA that dynamically reallocates the parameter budget based on importance scores.
- **DoRA (Liu et al., 2024a):** Decomposes pretrained weights into magnitude and direction, using LoRA for efficient directional updates.
- VeRA (Kopiczko et al., 2023): Employs a single pair of low-rank matrices across all layers to reduce trainable parameters.
- FourierFT (Gao et al., 2024): Fine-tunes models by learning a subset of spectral coefficients in the Fourier domain.
- AFLoRA (Liu et al., 2024b): Freezes low-rank adaptation parameters using a learned score, reducing trainable parameters while maintaining performance.
- LaMDA (Azizi et al., 2024): Fine-tunes large models via spectrally decomposed low-dimensional adaptation.
- **SSH (Shen et al., 2025b):** Fine-tunes large models after transforming weight matrices with the discrete Hartley transformation (DHT).
- MaCP (Shen et al., 2025a): Fine-tunes large models by projecting the low-rank adaptation weight change into the discrete cosine space.

We present experimental results on the GLUE benchmark with the RoBERTa-base model, following the settings from Shen et al. (2025b) and Shen et al. (2025a) and citing their reported baseline results for reference. The results in Table 19 indicate that BiDoRA consistently outperforms all baselines, including DoRA, across these diverse NLU tasks, demonstrating its robust generalization capability.

Table 19: Performance of various fine-tuning methods on the GLUE benchmark for the RoBERTa-base model. The evaluation metrics are Matthews Correlation Coefficient (MCC) for CoLA, Pearson Correlation Coefficient (PCC) for STS-B, and accuracy for all other tasks.

Model & Method	SST-2 (Acc.)	MRPC (Acc.)	CoLA (MCC)	QNLI (Acc.)	RTE (Acc.)	STS-B (PCC)	Avg.

DoRA $(r = 8)$	94.9	89.9	63.7	93.3	78.9	91.5	85.37
BiDoRA $(r = 8)$	95.7	90.2	65.8	93.4	79.4	90.5	85.83
DoRA $(r = 16)$	94.8	90.4	65.6	93.1	81.9	90.7	86.08
BiDoRA $(r = 16)$	95.0	90.8	66.7	93.3	82.6	90.9	86.55

H.2 Robustness of BiDoRA towards different rank settings.

We also explore the impact of different rank configurations on BiDoRA and DoRA, evaluating them with ranks of 8 and 16 in addition to the rank of 4 used in the main paper. Performance was assessed by fine-tuning RoBERTa-base on the GLUE benchmark, as detailed in Section 5.2. The average accuracies reported in Table 19 demonstrate that BiDoRA consistently surpasses DoRA across all rank configurations, highlighting its resilience and superior performance regardless of the rank setting.

H.3 Quantitative performance gap between training and testing set.

As visualized in Fig. 2, BiDoRA achieves a smaller gap between training and test performance. Here, we quantitatively present this performance gap on the RoBERTa-base model in Table 20. The training set metric is calculated as a moving average of the per-batch metric with a decay ratio of 0.99. Since BiDoRA has two training loops, its training metric is a weighted average ($0.8 \times$ inner-loop metric + $0.2 \times$ outer-loop metric), based on the data split size, inner : outer = 8 : 2, in our case. The results show that the performance gap for BiDoRA is consistently lower than that of DoRA across all datasets. This suggests that DoRA is more prone to overfitting, an issue that BiDoRA effectively addresses.

I Evidence on Orthogonality of Incremental Matrix

To verify that the orthogonal regularization (OR) proposed in Section 4.2 encourages the columns of the direction matrix to be orthogonal, we visualize the normalized eigenvalues of the matrix in Fig. 5. The results show that, compared to methods without OR (i.e., DoRA and BiDoRA w/o cst.), BiDoRA with OR produces eigenvalues that are more closely aligned with those of a purely orthogonal matrix, where all eigenvalues would be one. This effect holds for both the query and value matrices and verifies the effectiveness of the OR constraint.

Table 20: Quantitative performance gap between training and test sets for DoRA and BiDoRA using the RoBERTa-base model. The gap is calculated as the training metric minus the test metric, where a smaller value indicates less overfitting.

Method	SST-2	MRPC	CoLA	QNLI	RTE	STS-B	Avg.
DoRA	2.0	9.5	32.5	6.6	18.0	8.8	12.9
BiDoRA	1.7	7.0	23.3	0.2	14.0	4.7	8.5

Figure 5: Eigenspectra of the direction matrix for query (top) and value (bottom) matrices across different layers. The figure compares three fine-tuning methods: BiDoRA, BiDoRA without orthogonal regularization (w/o cst.), and DoRA. Both axes are on a log scale, and only the 64 largest eigenvalues are shown for visualization clarity. Experiments were conducted on the CoLA dataset (Warstadt et al., 2019) with the RoBERTa-base model.
