# FIRE : Flexible Integration of Data Quality Ratings for Effective Pretraining

Anonymous ACL submission

### Abstract

Selecting high-quality data can improve the pretraining efficiency of large language models (LLMs). Existing methods generally rely on heuristic techniques or single quality signals, limiting their ability to evaluate data quality comprehensively. In this work, we propose FIRE, a flexible and scalable framework for integrating multiple data quality raters, which allows for a comprehensive assessment of data quality across various dimensions. FIRE aligns multiple quality signals into a unified space, and integrates diverse data quality raters to provide a comprehensive quality signal for each data point. Further, we introduce a progressive data selection scheme based on FIRE that iteratively refines the selection of high-quality data points. Extensive experiments show that FIRE outperforms other data selection methods and significantly boosts pretrained model performance across a wide range of downstream tasks, while requiring less than 37.5% of the training data needed by the Random baseline to reach the target performance.

### 1 Introduction

019

021

024

025

027

042

Large language models (LLMs) have demonstrated remarkable performance by utilizing large-scale Transformers to pretrain on trillions of tokens. However, due to the constraints imposed by scaling laws (Kaplan et al., 2020), LLMs are quickly nearing their capacity and data limits. As a result, efforts to improve LLM performance have increasingly concentrated on optimizing the quality of pretraining data.

Numerous studies indicate that effective data selection can significantly enhance the convergence speed and generalization capability of LLMs (Engstrom et al., 2024; Wettig et al., 2024; Gao et al., 2025). Traditional methods predominantly rely on heuristic techniques, such as rule-based filtering (Rae et al., 2021; Raffel et al., 2020), deduplication (Abbas et al., 2023; Tirumala et al., 2024),

Figure 1: Downstream accuracy with respect to pretraining tokens for Random, FIRE, and FIRE Progressive.

and assessing proximity to high-quality corpora (Xie et al., 2023). Additionally, some work has focused on improving the evaluation of pretraining data quality by querying authoritative LLMs to determine whether the texts meet specific criteria (Wettig et al., 2024; Sachdeva et al., 2024).

Intuitively, assessing the quality of a text involves analyzing it across multiple dimensions. Nevertheless, the methods mentioned above evaluate data quality based on individual aspects, lacking a comprehensive assessment of the data's overall quality. Building on this limitation, the success of querying LLMs (Sachdeva et al., 2024) has inspired the straightforward idea of merging various quality rating criteria into a single prompt to collect comprehensive quality signals from authoritative LLMs. However, experimental findings show that this approach considerably weakens the performance of LLMs, as the excessive number of rules makes it challenging for LLMs to follow (further details can be found in Appendix E.2). The challenge of adhering to multiple rules underscores the necessity for a more sophisticated strategy to integrate various quality signals effectively.

In this paper, we propose FIRE, a Flexible and

scalable framework for Integrating multiple data quality Raters, designed to enable Effective pre-069 training of LLMs. Initially, we introduce an align-070 ment method to tackle the issue of inconsistent ratings from multiple raters. This method involves ranking the data based on the scores from the original raters and then partitioning it into quantiles. 074 We assess the probability that the data within each quantile is of higher quality (win rate) compared to a reference subset, using this probability as the 077 aligned rating. By fitting a win-rate-quantile curve for each rater, we effectively map the ratings from multiple raters into a unified rating space. Subsequently, to derive a comprehensive signal repre-081 senting the overall data quality, we integrate the aligned ratings of multiple raters, considering both the intrinsic reliability and orthogonality of the raters. Further, we introduce a progressive data selection scheme based on FIRE that iteratively refines the selection of high-quality data points, balancing computational complexity with the refinement of orthogonality.

> Extensive experiments demonstrate that by applying integrated ratings from multiple raters, our method achieves superior results across a variety of downstream tasks. Figure 1 illustrates that FIRE significantly enhances the pretrained model. We summarize our main contributions as follows:

(1) We propose FIRE, a flexible and scalable framework for integrating multiple data quality raters. FIRE aligns ratings from multiple raters into a unified space and integrates them to provide a comprehensive quality signal for each data point.

(2) We introduce a progressive data selection scheme based on FIRE that iteratively refines the selection of high-quality data points. It achieves a balance between computational complexity and the refinement of orthogonality.

(3) Extensive experiments demonstrate that FIRE enhances the pretrained model's performance by an average of 2.9%, while requiring less than 37.5% of the training data needed by the *Random* baseline to reach the target performance.

# 2 FIRE: Flexible Integration of Quality Ratings

### 2.1 Overview of the Method

We propose FIRE, a method that flexibly integrates
multiple raters to comprehensively evaluate data
quality. It involves two key processes: (a) Rating
Alignment and (b) Rater Integration. Figure 2

Figure 2: Overall framework of FIRE, which contains two processes: (a) Rating Alignment and (b) Rater Integration.

illustrates the overall framework of FIRE. Many off-the-shelf raters exist in practice. To be integrated by FIRE, a rater must provide a scalar score for each data point and be empirically validated for effectiveness. 118

First, we propose an alignment method to map ratings from multiple raters into a unified rating space. Specifically, we involve the probability that the data in each quantile is of higher quality (win rate) compared to a reference subset as the aligned rating. By fitting a win-rate-quantile curve for each rater, we effectively map the ratings from multiple raters into a unified rating space. It's worth noting that the alignment process allows us to quantify the intrinsic reliability of each rater, defined by the win rate of the best data subset selected by the rater relative to the reference subset, thereby reflecting the rater's performance.

We then integrate the aligned ratings of multiple raters, considering both the intrinsic reliability and orthogonality of the raters. We construct an orthogonality graph and calculate centrality through PageRank(Page et al., 1999) to quantify the independence among raters. The integrated rating is given by:

$$I(x) = \mathbf{A}(x)^T (\mathbf{o} \odot \boldsymbol{\gamma}) \tag{1}$$

where A(x) is the vector of aligned ratings for data point x, o is the overall orthogonality vector,  $\gamma$  represents the intrinsic reliability vector of the raters, and  $\odot$  denotes the element-wise product.

### 2.2 Rating Alignment

Aligning ratings from multiple data quality raters is crucial for achieving a credible integrated rater. This process involves standardizing ratings to a consistent scale and eliminating the significant differences in raters' high-quality thresholds, which

are the score thresholds that distinguish data contributing positively to pretraining. Appendix C.1 offers further analysis on the importance of rating alignment.

Given a pretraining dataset  $\mathcal{D}_t$  and multiple raters  $R_1, R_2, \ldots, R_n$ , we propose a method to consolidate these ratings into a unified rating space:

Step 1: Sample reference subset. Uniformly sample a subset  $\mathcal{D}_r$  from the pretraining data  $\mathcal{D}_t$ . It is worth noting that the data quality distributions of  $\mathcal{D}r$  and  $\mathcal{D}t$  are consistent. This consistency allows us to use  $\mathcal{D}r$  as a representative reference set: if a subset of data is of higher quality than data in  $\mathcal{D}r$ , it can be considered to exceed the typical quality of  $\mathcal{D}_t$ , and vice versa.

Step 2: Sort and partition data. Sort  $D_t$  according to  $R_i$ , and partition the sorted data into k intervals.

Step 3: Compare and calculate win rates. Randomly sample a subset  $\mathcal{D}_{ij}$  from each interval, ensuring that  $|\mathcal{D}_{ij}| = |\mathcal{D}_r|$ . Use GPT-40 (Islam and Moushi, 2024) to evaluate how the  $D_{ij}$  samples impact pretraining in comparison to the reference dataset  $\mathcal{D}_r$ . Then, calculate the win rate  $w_{ij}$  for each interval *j*:

$$w_{ij} = \frac{|\{x \in \mathcal{D}_{ij} \mid \text{GPT-4o: } x > y, y \sim \mathcal{D}_r\}|}{|\mathcal{D}_{ij}|}$$
(2)

where  $\mathcal{D}_{ij}$  signifies the subset sampled from the *j*-th rating interval for rater  $R_i$ . The win rate  $w_{ij}$ is the proportion of samples x in  $\mathcal{D}_{ij}$  that GPT-40 determines have higher quality than the comparison sample y from  $\mathcal{D}_r$ . Calculating win rates relative to  $\mathcal{D}_r$  makes ratings from multiple raters comparable. Moreover, since we sample only 1,000 data points per interval for comparison, the computational cost of this process remains low. The prompt for GPT-40 is detailed in Appendix C.2. We demonstrate the reliability of using GPT-40 for quality comparison in Appendix C.3.

Step 4: Fitting a win-rate-percentile function. Employ  $w_{ij}$  as the aligned rating for the midpoint of *j*-th rating interval of  $R_i$ , denoted by  $(p_j, w_{ij})$ . Construct a continuous win rate-percentile function from these coordinates using polynomial spline interpolation (detailed in Appendix C.4).

For any data point, we can find the aligned rating from a specific rater by applying the rater's win-rate-percentile function to its original rating and percentile. We apply the alignment method to the ratings of 4 raters on the SlimPajama dataset. The win rates in different percentiles and the fitted functions are provided in Appendix C.5. It is worth noting that since  $w_{i0}$  represents the win rate of the best data subset selected by rater *i* relative to the reference subset, it reflects the performance of rater *i* to a certain extent. Therefore, we can use  $w_{i0}$  as the intrinsic reliability of rater *i*, i.e.,  $\gamma_i = W_{i0}$ .

# 2.3 Rater Integration

Suppose for raters  $R_1, R_2, \ldots, R_n$ , each rater corresponds to a standard basis vector  $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$ in the quality space. The integrated quality vector  $\mathbf{q}(x)$  of data point x can be expressed as:

$$\mathbf{q}(x) = \sum_{j=1}^{n} \gamma_j A_j(x) \mathbf{v}_j \tag{3}$$

where  $\gamma_j$  denotes the intrinsic reliability of rater j,  $A_k(x)$  denotes the rating for data point x from rater  $R_k$  after alignment. Ideally, if  $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$  form an orthogonal basis, it is reasonable to measure the overall quality of the data using the L1 norm of q(x), as it represents the sum of the scores of data point x across various orthogonal quality dimensions. However,  $\mathbf{v}_1, \mathbf{v}_2, \ldots, \mathbf{v}_n$  are not necessarily completely independent. There may be raters  $R_i$ and  $R_i$  with a correlation coefficient  $\rho > 0$  and directly adding the corresponding aligned ratings would increase the weight of a particular quality dimension. To mitigate this issue, we define O(i, j)to quantify the orthogonality of two raters i and j(the formalization of O(i, j) can be found in Appendix C.6). For a rater  $R_i$ , we apply the sum of its orthogonality with all other raters to weight its rating. If a rater is highly correlated with others, we use a lower orthogonality to penalize. So the integrated rating for data point x can expressed as

$$I(x) = \sum_{j=1}^{n} \gamma_j o_j A_j(x) \tag{4}$$

where  $o_j = \sum_{\substack{k=1 \ k \neq j}}^n O(j,k)$  is a quantification of the overall orthogonality  $R_i$  with other raters.

Inspired by Equation (4), we find that integration of ratings weighted by orthogonality can be formalized to the centrality problem of graph theory. Formally, we define orthogonality graph of a rater as follows:

Definition 1 (Orthogonality Graph). An orthogonality graph is a complete graph where the vertices

- 254 258 261 262
- 263
- 265
- 267

274 275

276

279

281

287

282

where  $\|\cdot\|_2$  denotes the Euclidean Norm. In this paper we set  $\alpha = 50$  since  $o_{\alpha}$  tends to stabilize after 50 iterations. The justification for employing

result, our final formula becomes:

Equation (7) and (8) to quantify the overall orthogonality is provided by Theorem 3 in Appendix  $B^{1}$ . Final version of the integrated rating for data

 $V_i$  represent the raters  $R_i$ . The weight of the edge

between two vertices is the orthogonality O(i, j)

Based on Definition 1, we provide the following

**Theorem 1.** The overall orthogonality  $o_i$  of a rater

 $R_i$  with other raters can be quantified as weighted

degree centrality of the corresponding vertex  $V_i$  in

We give Theorem 1's proof in Appendix B. Let

 $\mathbf{o} = [o_1, o_2, \dots, o_n]^T$  denote the overall orthogo-

nality vector, where  $o_i$  represents the overall or-

thogonality of rater  $R_i$ . Define M as the adja-

cency matrix of the orthogonality graph, such that

 $\mathbf{M}_{ij} = O(i, j)$ . Additionally, let 1 be the all-ones

 $\mathbf{o}^{(0)} = \mathbf{M1}$ 

Considering that in a multi-rater setting, the in-

dependence of  $R_i$  might be affected by the orthog-

onality between different raters  $R_i$  and  $R_k$ , we pro-

pose an iterative formula, analogous to PageRank

 $\mathbf{o}^{(k+1)} = d\mathbf{M}\mathbf{o}^{(k)} + (1-d)\mathbf{1}$ 

where d is the damping factor and k denotes the k-

th iteration. In PageRank, node centrality depends

on edge weights. Since FIRE defines edge weights

via orthogonality, the resulting scores reflect each node's overall independence. Since the introduc-

tion of the damping factor aims to address the rank

sinks problem, which is not present in our graph,

we find it reasonable to set d = 1. Assuming the

number of iterations is  $\alpha$ , and normalizing the final

 $\mathbf{o}_{\alpha} = \mathbf{M}^{\alpha} \mathbf{o}^{(0)}$ 

 $\mathbf{o} = rac{\mathbf{o}_{lpha}}{\|\mathbf{o}_{lpha}\|_2}$ 

vector. We can then derive the following:

between the two raters.

the orthogonality graph.

(Page et al., 1999):

theorem:

point x can be expressed as:

$$I(x) = \mathbf{A}(x)^T (\mathbf{o} \odot \boldsymbol{\gamma}) \tag{9}$$

#### 3 **Progressive Data Selection via FIRE**

The most intuitive data selection method involves ranking the integrated ratings based on FIRE for the pretraining dataset, and then selecting the top k highest-rated data points. Nonetheless, our analysis shows that after ranking  $\mathcal{D}_t$  based on the integrated ratings, there is a change in the overall orthogonality o calculated from data subsets in different quantiles (Figure 9). The phenomenon arises because the top data better reflects the quality emphasized by the raters, while the tail data often contains more noise and low-quality information, leading to changed orthogonality among the raters. To refine the data selection process and mitigate the coarseness introduced by computing orthogonality on the entire dataset, we propose a progressive data selection scheme based on FIRE.

Specifically, as shown in Algorithm 1, we first calculate the integrated ratings for the data points in  $\mathcal{D}_t$  based on FIRE, then sort the data points, but we don't select them right away based on these ratings.

Table 1: Downstream tasks results for different rating integration method. We report accuracy for each task, and the best performances are marked in bold. For rater integration, we report the average score of all the combinations. Detailed results can be found in the Appendix E.1. Abbreviations: HellaSw. = HellaSwag, W.G. = WinoGrande, AVG. = Average, W.S. = Writing Style, R.E. = Required Expertise, F.T. = Facts and Trivia, E.V. = Educational Value, Prg = Progressive, Comp. = Comprehensive. †: We implement the method from QuRating(Wettig et al., 2024).

It is reduced to  $\eta\%$  of its original size by selecting the top  $\eta\%$  of data based on integrated ratings. Then, the data is partitioned into *n* segments based on integrated ratings' quantiles. Orthogonality is computed within each segment to determine refined integrated ratings. After sorting the data according to new ratings, it's further reduced to  $\eta\%$  of its initial size. The number of segments is increased by a factor of  $\beta$ , unless it reaches the maximum threshold  $n_{max}$ , in which case the data is divided into  $n_{max}$  segments. The iterative process of calculating orthogonality within progressively smaller subsets continues before the subsequent reduction leaves less than k data points for selection.

### 4.1 Experimental setup

Setup We use SlimPajama (Soboleva et al., 2023) as the selection pool, with a total scale of 627B. And we employ the Llama (Touvron et al., 2023) tokenizer to divide the entire dataset into sequences of length 1024. During the data selection process, we select the top portion of data with the highest rating. For integrating different raters, we carry out experiments based on the four single raters of QuRating (Wettig et al., 2024): Writing Style, Facts and Trivia, Educational Value, and Required Expertise. For progressive data selection (FIRE Progressive), we set  $\eta = 60, \beta = 20$ . For model training, we train a model with 1.3B parameters for 10,000 steps (equivalent to 20B tokens) and a 3B model for 200B tokens, with bfloat16 format during both training and testing.

**Evaluation** We utilize Im-evaluation-harness (Gao et al., 2021) to assess the models' performance across eight downstream tasks: ARC-E (Clark et al., 2018), ARC-C (Clark et al., 2018), SciQ (Welbl et al., 2017), LogiQA (Liu et al., 2020), BoolQ (Clark et al., 2019), HellaSwag (Zellers et al., 2019), PIQA (Bisk et al., 2020), and WinoGrande (Sakaguchi et al., 2021). We employ in-context learning for the evaluation, selecting enough examples to fill the window length of 1024 tokens for each task. Standard accuracy metrics are reported for all tasks.

**Baselines** In addition to comparing FIRE with four single raters from Qurating, we also compare it with the following methods: (1) *Random*: randomly selecting data from the original training corpus. (2) *DSIR* (Xie et al., 2023): utilizing importance sampling for data selection, and we chose Wikipedia and Books as target domains. (3) *Density* (Sachdeva et al., 2024): using KDE to estimate data density in the training corpus and employing inverse sampling. (4) *ASK-LLM* (Sachdeva et al.,

2024): using a comprehensive prompt to label highquality data, and train a T5-based classifier.

Furthermore, we compare several basic rating integration methods: (1) *Comprehensive Rater*: integrating multiple single rater criteria into a single prompt to obtain annotations from GPT-40, then training a comprehensive quality rater. (2) *Max Criteria*: aligning ratings and selecting the highest value in each dimension as the final rating. (3) *Average*: arithmetic mean integration of normalized ratings from each rater. (4) *Mix Criteria*: we follow QuRating(Wettig et al., 2024) to merge and deduplicate the top data selected by each single rater, followed by random sampling. These four methods are applied to the integration of four raters. More details can be found in Appendix D.2.

#### 4.2 Main Results

370

371

375

384

Table 1 show our main results. We find that:

FIRE is superior to other integration methods. FIRE demonstrates greater effectiveness than existing integration methods, while introducing minimal additional computational cost (see Appendix D.3 for a detailed analysis of computational cost). As shown in Table 1, Comprehensive Rater with a multi-dimension prompt results in an average score that is even lower than the single-dimension rater Facts and Trivia. This suggests that GPT-40 still 397 falls short in assessing data quality from a broad perspective. Both Mix Criteria and Max Criteria are inferior to FIRE, indicating that a comprehensive evaluation of FIRE is more beneficial. Aver-400 age simply calculates the mean of all ratings and 401 the experimental results of FIRE demonstrate an 402 improvement over Average. To demonstrate the 403 robustness of FIRE, we conduct additional experi-404 ments integrating other raters. Detailed results are 405 provided in Appendix D.4. 406

FIRE outperforms the single raters and other 407 data selection methods. Comparing FIRE to the 408 individual raters, it demonstrates significant im-409 provements, with an average score increase of up 410 to 1.9% over the best single rater and 2.9% over 411 random selection. From a data efficiency perspec-412 tive, FIRE achieves comparable performance using 413 414 less than 37.5% of the data required by the Random baseline. Additionally, our method outper-415 forms QuRating and other data selection methods, 416 validating the high quality of the data selected by 417 FIRE. 418

Figure 3: Ablation experiments on the impact of different rating integration strategies in FIRE.

Adding more raters can lead to better performance. We observe that as the number of integrated raters increases, the overall effect gradually improves. The average score of FIRE with three raters surpasses that of the integration of two raters, and further increases when four raters are integrated. This indicates that our rater integration method is scalable: incorporating a broader range of raters not only provides a more comprehensive evaluation of the samples but also allows for a better understanding of the importance of each metric. 419

### Progressive selection further improves FIRE

After integrating progressive selection, we observe a notable improvement in the model's performance on downstream tasks. Compared to FIRE (4 Raters), the average score of FIRE (4 Raters) Prg. increases by 0.4%. The most significant improvement is seen in PIQA, with an absolute score boost of 2.7%. These results validate the effectiveness of the progressive selection method in choosing high-quality data.

### 4.3 Analysis

**Ablation Study** We integrate four single raters, and subsequently remove *Rating Alignment* (*Align.*), *Intrinsic Reliability (Rel.*), and *Orthogoality (Orth.*), as well as remove all (directly averaging on the rating post-normalization), in order to investigate the impact of each component in FIRE.

From Figure 3, we can find that: (1) Rating alignment is a crucial step. We note that without rating alignment, the score drops by 3.3%, even falling below the direct average. As we previously detailed, the alignment allows for better comparability between the ratings from different raters, making their integration more reasonable. (2) Both orthogonality and intrinsic reliability can further enhance model performance, with the impact of orthogonality being relatively significant (a drop of 2% w/o Orth.), while the improvement from Intrinsic Reliability is rather subtle (a drop of 0.2% w/o

Figure 4: The in-context learning results with respect to pretraining tokens on four downstream tasks: ARC-E, ARC-C, SciQ, and HellaSwag.

Rel.) (3) The combination of all components yields the best results. This implies that these methods of integrating the ratings are complementary. By superimposing both methods, we can achieve a rating that more accurately reflects the actual contribution of the sample to the pretraining.

475

476

477

478

479

480

**Training Efficiency** Figures 1 and 4 show how the model's performance on downstream tasks evolves with the pretraining tokens. In terms of average score, our method outperforms the random baseline by 2.9%. From the training efficiency perspective, our method reduces training tokens to achieve a certain performance level by more than half. In addition, our method shows a significant advantage in the ARC-E/C and SciQ tasks, consistently scoring higher than the random baseline. However, on the HellaSwag task, our method's performance is similar to the random baseline and does not consistently surpass it. One possible explanation is that HellaSwag is an especially challenging dataset, which makes it difficult to discern performance differences on the 1.3B scale model.

Larger datasets and models To validate our 481 method on larger models and datasets, we con-482 duct several additional experiments: (1) Training 483 a 1.3B parameter model for 40B tokens using ran-484 485 domly sampled data; (2) Training a 3B parameter model for 200B tokens for both random sampling 486 and FIRE (four raters integration). As illustrated in 487 Table 2, the results indicate that the FIRE method 488 outperforms Random with fewer training FLOPS 489

| Method          | Pretraining FLOPS    | ARC-C | HellaSwag | AVG. |  |  |  |  |  |
|-----------------|----------------------|-------|-----------|------|--|--|--|--|--|
| Model Size      | e = 1.3B             |       |           |      |  |  |  |  |  |
| Random          | $32.2\times10^{19}$  | 23.6  | 34.4      | 48.6 |  |  |  |  |  |
| FIRE            | $16.1\times10^{19}$  | 26.4  | 32.9      | 50.0 |  |  |  |  |  |
| Model Size = 3B |                      |       |           |      |  |  |  |  |  |
| Random          | $377.5\times10^{19}$ | 26.8  | 49.4      | 54.1 |  |  |  |  |  |
| FIRE            | $377.5\times10^{19}$ | 28.8  | 51.7      | 55.7 |  |  |  |  |  |

Table 2: Experimental results on larger models and datasets.

Figure 5: The impact of the partition multiplier factor  $\beta$  on FIRE Progressive performance. The red and orange dashed lines respectively represent the scores of FIRE and Random.

in the 1.3B parameter model setting. Furthermore, in the 3B parameter model setting, FIRE exceeds *Random* by an average of 1.6%, demonstrating the robustness and scalability of our method with larger models and training datasets.

Ablation Study for Progressive Selection We conduct an ablation study on the partition multiplier factor  $\beta$  for the FIRE Progressive approach, with the outcomes shown in Figure 5. The results show that for a majority of  $\beta$  values, FIRE Progressive scores surpass those of FIRE and Random, suggesting that the progressive selection method contributes to a consistent enhancement of the FIRE framework.

**Case study** We extract 1M samples from the corpus and compute the pairwise Pearson correlation of the ratings across all dimensions. As illustrated in Figure 6a, the FIRE rating exhibits a strong correlation with all other ratings, confirming the effectiveness of the FIRE framework in consolidating ratings across multiple dimensions. By employing the FIRE framework, we can effectively select data that exhibits high ratings across all dimensions.

Moreover, we analyze the data properties that FIRE focuses on compared to other raters. Based on the four dimensions in QuRating and a compre-

Figure 6: (a) The Pearson correlation between different raters. (b) Illustration of top samples rated by each method. We use Sentence-T5 to encode texts, and employ t-SNE to perform dimensionality reduction.

| Rater/Dimension | W.S.        | R.E.        | F.T.        | E.V.        | Comp. |
|-----------------|-------------|-------------|-------------|-------------|-------|
| W.S.            | 94.0        | 53.5        | 62.9        | 25.6        | 84.1  |
| R.E.            | 39.0        | 85.8        | 93.8        | 97.1        | 98.0  |

hensive dimension, we determine the percentage of high-quality data selected by each rater in each dimension. We pick 1000 data points at random from the top 20B data that are selected by each method. Then we use GPT-40 to assess each dimension six times, taking the average as the final evaluation result. Refer to the Appendix D.5 for more details. As shown in Table 3: (1) From a comprehensive perspective, FIRE shows the best results, as evidenced by our performance in downstream tasks.
(2) In terms of each dimension, FIRE consistently achieves relatively high accuracy, demonstrating that the data selected by this method maintains high quality across all dimensions.

To assess whether FIRE selects more diverse samples than single raters, we extract the top 1000 texts from each method and encode them using Sentence-T5 (Ni et al., 2022). We then apply t-SNE (Van der Maaten and Hinton, 2008) for dimensionality reduction and visualize the results in Figure 6b. In the latent semantic space, samples selected by single raters appear more clustered, while those selected by FIRE are more broadly distributed, indicating higher diversity. Combined with prior case studies showing high quality, FIRE demonstrates a strong balance between diversity and quality.

# 5 Related Works

When pretraining language models, a large amount of text corpus is often crawled from the internet. However, several studies (Li et al., 2023; Zhou et al., 2024; Duan et al., 2025) suggest that highquality data is more beneficial to the model's performance. To select high-quality data, a common strategy involves utilizing rules crafted by experts (Raffel et al., 2020; Rae et al., 2021; Laurençon et al., 2022; Computer, 2023; Penedo et al., 2024) and removing duplicate sentences (Lee et al., 2022; Sorscher et al., 2022; Abbas et al., 2023; Soboleva et al., 2023; Tirumala et al., 2024). However, they often fall short in effectively selecting high-quality data based on semantic content. An alternative approach involves utilizing a target data source or proxy model (Wenzek et al., 2020; Xie et al., 2023; Marion et al., 2023; Thakkar et al., 2023; Engstrom et al., 2024; Yu et al., 2024).

Training a classifier is a more straightforward method (Du et al., 2022; Gururangan et al., 2022; Zhang et al., 2024; Wettig et al., 2024; Sachdeva et al., 2024). Du et al. (2022) implemented a logistic regression binary classifier to score the data, while some studies train more complex scorers (Zhang et al., 2024; Sachdeva et al., 2024). Additionally, QuRating (Wettig et al., 2024) trains multiple raters with a finer-grained approach to analyze the contribution of data to model performance improvement from different dimensions. Other studies(Zhang et al., 2025b,a) explore methods to boost pretraining efficiency by curriculum learning.

Prior methods mainly select data from a single perspective. Although QuRating introduces multidimensional raters, it does not systematically address their integration—a challenge our work explicitly tackles.

## 6 Conclusion

We propose FIRE, a flexible and scalable framework that integrates multiple data quality raters for comprehensive, multi-dimensional data assessment. First, ratings from different dimensions are aligned into a unified space. Then, orthogonality is introduced to adjust rater weights. To handle orthogonality variations across rating ranks, we adopt a progressive approach for fine-grained data selection. Experiments on the SlimPajama dataset show that FIRE outperforms other selection methods, substantially improving pretrained model performance across diverse downstream tasks.

### 7 Limitations and Future Works

Linear assumption for orthogonality integration
We hypothesize our integration on a linear additive relation. While this assumption simplifies the
computations, it might limit our ability to capture
complex interactions between different dimensions.
Future research could explore incorporating nonlinear systems to adjust rater weights, potentially
boosting performance.

**Number of raters** We've tested our method with four different raters and the results have been promising. To make our integration method more robust and reliable, future tests could include more raters from diverse dimensions, which would ultimately help us build a more resilient and versatile rating integration system.

# A Ethical Considerations

Training large language models (LLMs) demands a substantial amount of electrical power, resulting in significant carbon emissions. To address this issue, we aim to develop efficient data selection methods that reduce the computational resources required for model training, thereby mitigating environmental impact. Furthermore, by meticulously curating high-quality data, we can enhance model performance and minimize the occurrence of hallucinations. This not only improves the reliability of the models but also helps curb the spread of fake news and misinformation, addressing critical societal concerns. 818

### **B Proof of theorems**

In this section, we present the proofs for the two previously mentioned theorems. Theorem 2 facilitates the transformation of orthogonality calculations into a centrality problem within a graph. Meanwhile, Theorem 3 rigorously demonstrates the convergence of our framework. Specifically, it establishes that after several iterations, the vector  $\frac{\mathbf{o}}{||\mathbf{o}||_2}$  will assuredly converge to a fixed vector, thus precluding divergence.

**Theorem 2.** The overall orthogonality  $o_i$  of a rater  $R_i$  with other raters can be quantified as weighted degree centrality of the corresponding vertex  $V_i$  in the orthogonality graph.

*Proof.* Consider that the weighted degree centrality of vertex  $V_i$  is the sum of the weights of the edges connecting  $V_i$  to all vertices in the set of adjacent vertices  $A_i$ . Since the graph of orthogonality is a complete graph, we have

$$C(V_i) = \sum_{V_j \in A_i} O(i, j) = \sum_{\substack{j=1 \\ j \neq i}}^n O(i, j)$$

This is consistent with the definition of the overall orthogonality in Equation (4) of the main text.  $\Box$ 

**Theorem 3.** As  $\alpha \to +\infty$ , o will eventually converge to a fixed unit vector.

*Proof.* Since the Graph of orthogonality is an undirected graph, the adjacency matrix M is a symmetric matrix. According to the Spectral Theorem for Symmetric Matrices, M can be diagonalized, and all corresponding eigenvectors can form an orthogonal basis. Since for any  $i, j, O(i, j) \ge 0$ , we can deduce that M is a non-negative matrix. Additionally, since the Orthogonality Graph is a complete graph, M is an irreducible matrix. By the Perron-Frobenius Theorem, we obtain that:

$$\exists \lambda \in \mathbb{R}, \lambda > 0$$
  
s.t.  $\lambda = \max \{ \mu \mid \mu \in \sigma(\mathbf{M}) \},$ 

where  $\sigma(\mathbf{M})$  denotes the set of eigenvalues of M. Assume M has m eigenvalues  $\lambda_1, \lambda_2, ..., \lambda_m$ arranged in descending order, where  $\lambda_1 > 0$ . Each eigenvalue  $\lambda_i$  corresponds to the eigenvectors  $\mathbf{v}_{i1}, ..., \mathbf{v}_{ip_i}$ , where  $p_i$  is the algebraic multiplicity of  $\lambda_i$ . We can decompose  $\mathbf{o}^{(0)}$  into each eigenvector

876 
$$\mathbf{o}^{(0)} = \sum_{i=1}^{m} \sum_{j=1}^{p_i} c_{ij} \mathbf{v}_{ij}$$

877 Therefore, we have

$$\mathbf{M}^{\alpha} \mathbf{o}^{(0)} = \mathbf{M}^{\alpha} \sum_{i=1}^{m} \sum_{j=1}^{p_{i}} c_{ij} \mathbf{v}_{ij}$$
$$= \sum_{i=1}^{m} \sum_{j=1}^{p_{i}} c_{ij} \mathbf{M}^{\alpha} \mathbf{v}_{ij}$$
$$= \sum_{i=1}^{m} \sum_{j=1}^{p_{i}} c_{ij} \lambda_{i}^{\alpha} \mathbf{v}_{ij}$$
$$= \lambda_{1}^{\alpha} \sum_{i=1}^{m} \sum_{j=1}^{p_{i}} c_{ij} (\frac{\lambda_{i}}{\lambda_{1}})^{\alpha} \mathbf{v}_{ij}$$

Given that  $\forall i \neq 1, |\frac{\lambda_i}{\lambda_1}| < 1$ , thus

$$\lim_{lpha
ightarrow+\infty}\left(rac{\lambda_i}{\lambda_1}
ight)^lpha=0$$

We obtain

$$\mathbf{o} = \lim_{\alpha \to +\infty} \mathbf{M}^{\alpha} \mathbf{o}^{(0)} = \lambda_1^{\alpha} \sum_{j=1}^{p_1} c_{1j} \mathbf{v}_{1j}$$

Thus

$$\frac{\mathbf{o}}{||\mathbf{o}||_2} = \frac{\lambda_1^{\alpha} \sum_{j=1}^{p_1} c_{1j} \mathbf{v}_{1j}}{||\lambda_1^{\alpha} \sum_{j=1}^{p_1} c_{1j} \mathbf{v}_{1j}||_2}$$
$$= \frac{\sum_{j=1}^{p_1} c_{1j} \mathbf{v}_{1j}}{||\sum_{j=1}^{p_1} c_{1j} \mathbf{v}_{1j}||_2}$$

The right-hand side of the formula is a fixed unit vector. Therefore, the theorem is proven.  $\Box$ 

## C FIRE Analysis

# C.1 Analysis of the necessity of rating alignment

Multiple raters may employ different scales and criteria for assessing data quality, which can cause substantial problems if their ratings are integrated without appropriate standardization. For example, some raters may prioritize grammatical accuracy using a numerical scale, while others might assess semantic relevance using a percentage scale. Moreover, the rating thresholds distinguishing data that positively contribute to pretraining can significantly differ among raters. Without rating alignment, the integrated ratings can be misleading, inaccurately reflecting the actual quality of the data point. The subsequent examples and analyses underscore the importance of rating alignment for a reasonable data quality evaluation:

- Different Scales. Suppose we have Rater A, who assesses data quality on a 1 to 10 scale based on grammatical accuracy, and Rater B, who evaluates semantic relevance on a 0% to 100% scale. Let's say a particular data point receives an 8 from Rater A and 85% from Rater B. If we naively average these ratings, we get:  $\frac{8+85}{2} = 46.5$ . This score does not genuinely reflect the data quality as the scales used are inherently different. Hence, it is crucial to standardize the ratings onto a common scale to facilitate meaningful comparisons.
- · Different Quality Thresholds. Even with rat-917 ings standardized to a common scale, we face 918 the problem of varying quality thresholds dis-919 tinguishing data that positively contribute to 920 pretraining. For example, Rater A may deem 921 ratings above 5 as high-quality, whereas Rater 922 B may view ratings above 80% as high-quality. 923 Suppose we standardize both ratings to a 0-924 1 scale, turning an 8 from Rater A into 0.8 925 and 85% from Rater B into 0.85. Despite this 926 standardization, direct comparison of the two 927 raters' scores remains impractical due to their 928 differing threshold values for differentiating 929 data quality. 930

Polynomial spline interpolation for

To obtain the aligned rating for each data point,

we consider the win rate  $w_{ij}$  of rater *i* in the *j*-th

rating interval as the rating of the midpoint of that

interval, denoted by coordinates  $(p_i, w_{ij})$ . We then

complete the rater's win-rate-percentile function

using polynomial spline interpolation to derive a

continuous and smooth win-rate-percentile func-

tion. The polynomial spline interpolation function

win-rate-percentile function

further reduces bias.

S(p) is defined as follows:

**C.4** 

where p denotes the percentile,  $p_k$  and  $p_{k+1}$  are the boundaries of the k-th interval, n is the degree of the polynomial, and  $a_k, b_k, \dots, y_k, z_k$ , and  $d_k$ are the coefficients determined through the spline interpolation process.

# C.5 Ratings distribution illustration

Figure 7 shows the win rates of samples in different percentile intervals and the fitted Rating-Percentile curves for 4 raters. The original ratings provided by the four raters exhibit significant differences, as illustrated in Figure 4 of QuRating(Wettig et al., 2024). The alignment introduces a random subset for comparison, which makes the ratings from different raters comparable, mapping the ratings into a similar range. This forms the foundation for the subsequent weighted integration of the raters, which explains the poor performance without alignment. However, even after alignment, there are still noticeable differences in the rating distributions of different raters. For instance, in Figure 7a and 7c, there are significant differences in the win rate of the first quartile and the middle section of the curve.

# C.6 Formalization of Orthogonality.

**Empirical determination of the boundary conditions.** For convenience and without losing rationality, we use the initial version of the integrated

# C.2 Prompt for GPT-40 to compare data quality

# Prompt for GPT-40 to compare data quality

Compare two text excerpts and choose the text which contain more informative signal for pretraining a large–language model.

An informative datapoint should be well– formatted, contain some usable knowledge of the world, and strictly NOT have any harmful, racist, sexist, etc. content. Aspects that should NOT influence your judgement:

1. The length of the text

2. The order in which the texts are presented

Note that the texts are cut off, so you have to infer their contexts. The texts might have similar quality, but you should still make a relative judgement and choose the label of the preferred text.

[Option A] ... {text a} ... [Option B] ... {text b} ...

Now you have to choose between either A or B. Respond only with a single word.

# C.3 Reliability Analysis of GPT-40

QuRating(Wettig et al., 2024) points out that GPT is more effective at comparing the relative quality between two data samples than performing absolute quality evaluation. To further assess the reliability of GPT-40, we use QuRating (Educational Value) as a case study and conduct a win-rate evaluation involving human experts. Specifically, we compare the win rates assigned by human annotators and GPT-40 across different rating percentiles, with results presented in descending order of percentile rating in Table 4. The two sets of win rates exhibit a Pearson correlation of 0.99, indicating strong agreement and suggesting that GPT-40 does not introduce significant bias in the annotation process. This high consistency supports the reliability of using GPT-40 for quality assessment. Further-

rating calculation formula (without PageRank optimization) to determine the boundary values of orthogonality. The integrated rating of data point *i* can be expressed as

994

995

997

998

999

1001

1002

1003

1004

1005

1007

$$I(i) = \sum_{j=1}^{n} \gamma_j o_j A_j(i)$$

where  $o_j = \sum_{\substack{k=1 \ k \neq j}}^n O(j, k)$  is a quantification of the overall orthogonality  $R_j$  with other raters. We ignore the impact of raters' reliability and set  $\gamma_j = 1$ . By substituting the definition of the overall orthogonality, we obtain

$$I(i) = \sum_{j=1}^{n} \left( \sum_{\substack{k=1\\k\neq j}}^{n} O(j,k) \right) A_{j}(i)$$

$$= \frac{1}{2} \sum_{j=1}^{n} \sum_{\substack{k=1\\k\neq j}}^{n} O(j,k) \left( A_{j}(i) + A_{k}(i) \right)$$
(11)

The final expression, after rearrangement, can be seen as pairwise addition of raters, with their integrated ratings weighted by the orthogonality of the two raters. When two raters are perfectly cor-1008 related, it means their ratings are identical across 1009 all data points. In this scenario, the information 1010 provided by one rater is entirely redundant with 1011 respect to the other. Therefore, the orthogonality 1012 between these raters should be set to 0, indicating 1013 no additional information is gained by consider-1014 ing both ratings. Conversely, when two raters are 1015 perfectly orthogonal, it signifies that their ratings 1016 are completely independent of each other. Each 1017 rater offers unique and complementary perspec-1018 tives, leading to a comprehensive evaluation when 1019 combined. In such cases, the orthogonality should 1020 be set to 0.5, reflecting that each rater contributes 1021 equally distinct information to the overall rating.

**Orthogonality function.** The most intuitive approach to determine the orthogonality between two raters is to use the correlation coefficient between their rating distributions on a pretraining dataset. The orthogonality-correlation function needs to satisfy two key conditions:

1023

1024

1025

1026

1027

1030

1031

1032

1034

1035

1036

- **Monotonicity:** The stronger the correlation, the lower the orthogonality.
- **Boundary Conditions:** Empirically, when two raters are completely uncorrelated, the orthogonality between them is 0.5; when they are fully correlated, the orthogonality is 0. And the empirical value has been described above.

In fact, we choose the orthogonality between 1037 two raters to be 0 when they are completely cor-1038 related, as we want to avoid duplication issues during rater integration. For instance, consider 1040 three raters, where Rater 1 and Rater 2 are com-1041 pletely correlated (correlation coefficient of 1) and 1042 are completely uncorrelated with Rater 3 (correla-1043 tion coefficient of 0). Considering only one itera-1044 tion, the integration result of the three raters is R =1045  $O_{12}(R_1+R_2)+O_{13}(R_1+R_3)+O_{23}(R_2+R_3) =$ 1046  $(O_l + O_h)R_1 + (O_l + O_h)R_2 + 2O_hR_3$ , where  $O_l = O_{12}, O_h = O_{13} = O_{23}$ . Given that Rater 1 1048 and Rater 2 are completely correlated, which means  $R_1 = R_2$ , we obtain  $R = 2(O_l + O_h)R_1 + 2O_hR_3$ . If  $O_l \neq 0$ ,  $R_1$  will be assigned an additional weight. However, one would naturally assume that  $R_1$  and  $R_3$  should carry the same weight when they are completely uncorrelated.

1049

1050

1052

1054

1055

1056

1057

1058

1059

1081

1082

1084

1085

1086

1088

1090

1092

Considering the scenario where the correlation coefficients among all raters are zero, the calculation of orthogonality would completely degenerate to zero. Therefore, in such extreme cases, we treat all perfectly correlated raters as a single rater and do not proceed with orthogonality-related integration.

Based on the conditions, we explored three functional forms that satisfy the criteria: a linear function, a Gaussian function, and a symmetrically processed Gaussian function. The three functional forms explored for orthogonality are as follows:

(1) Linear Function:

$$O_L(i,j) = \frac{1}{2} \cdot (1 - |r(i,j)|)$$
(12)

(2) Gaussian Function:

$$O_G(i,j) = \exp\left(-\frac{r(i,j)^2}{2c^2}\right) - \frac{1}{2}$$
 (13)

# (3) Symmetrically Processed Gaussian Function:

$$O_{S,G}(i,j) = \left(\frac{3}{2} - |r(i,j)|\right) - \exp\left(-\frac{r(i,j)^2}{2c^2}\right)$$
(14)

where r(i, j) represents the correlation measure between raters *i* and *j*. Specifically, it is quantified using the Pearson correlation coefficient between the score distributions of the two raters over a common dataset. In both Gaussian-based functions, the constant  $c = \sqrt{\frac{1}{2\ln 2}}$  is determined by the boundary conditions. Figure 8 illustrates the 3 forms of orthogonality functions with respect to correlation coefficient.

It's worth noting that the experiments in Appendix E.3 demonstrate that the symmetrically processed gaussian function exhibits the best performance. Therefore, in the main experiments of this paper, we use the symmetrically processed gaussian function, i.e., Equation (14). Additionally, when integrating the ratings from two raters, their weights based on orthogonality are the same. Therefore, we only use the intrinsic reliability of the raters to weight their ratings.

### **D** Experimental Details

#### D.1 Model and training

We train a model with 1.3B parameters similar to 1100 the Llama architecture, the model structure is de-1101 tailed in the Table 5. We train the language model 1102 from scratch and randomly initialize the model 1103 parameters. We set the batch size to 2048 and 1104 the learning rate to 5e-4, using a cosine learning 1105 schedule. To accelerate the training and inference 1106 processes, we use the bfloat16 format during both 1107 training and testing. The training is based on the 1108 Megatron framework and utilizes flash attention. 1109 The entire model is trained on 16 A100 GPUs for 1110 a total of 10,000 steps. For FIRE orthogonality 1111 calculation, we use the symmetrically processed 1112 gaussian function. 1113

#### **D.2** Integration Baselines

We compare our rating integration method with1115other baseline methods. Here we give more details1116about the baselines.1117

Figure 9: Trends of orthogonality functions with the change in percentile of different pairs of raters.

[Option A] {text1} [Option B] {text2}

Now you have to choose between either A or B. Respond only with a single word.

Comprehensive RaterFollowing QuRating1119(Wettig et al., 2024), we collect pairwise comparison data and train a reward model based on1120Sheared-Llama 1.3B (Xia et al., 2023). We merge1122all the evaluation criteria into a single prompt to1123guide GPT-40 comparison. Above is an illustration1124of the prompt.1125

1143

1144

1145

1146

1147

1148

1158

**Mix Criteria** We utilize each rater to select the top 20B tokens, which are then merged and duplicates removed. Following this, we randomly pick out another 20B tokens from this merged set. As each sample only requires to excel in one rater's evaluation to be considered for selection, this approach emphasizes the dimension in which the sample performs best amongst all dimensions.

**Max Criteria** Once the scores are aligned, we directly select the dimension with the highest rating to represent the integration result. This method is analogous to performing max-pooling across all dimensions, straightforwardly highlighting the dimension within the sample that has the highest rating.

**Average** For multi-rater integration, the most straightforward approach is to assume that each rater contributes equally to the overall quality of the data. Accordingly, we normalize the ratings provided by each rater for the samples. Following normalization, the average of these ratings is computed to obtain the final integrated rating.

# D.3 Analysis of Computational Cost

This section analyzes the computational cost (mea-1149 sured in FLOPs) for various data rating and integra-1150 tion methods. The focus is on the cost introduced 1151 by applying raters to the pre-training data, exclud-1152 ing the main model's training cost. FIRE achieves 1153 more effective integration without introducing sig-1154 nificant extra cost beyond the base raters. The 1155 FLOPs comparison is summarized in Table 6. 1156 The analysis includes: 1157

- 1. Rater training (if applicable),
- 2. Rater inference over the entire dataset, 1159
- 3. Additional computation for FIRE's win-ratebased integration. 1160

QuRating (Single Rater).Each QuRating model1162is a 1.3B-parameter transformer.It is first fine-1163tuned on 500K examples (512 tokens each).The1164

| Method                               | FLOPs                         |

|      |   |

$$FLOPs_{train} \approx 6 \cdot N \cdot d^2 \cdot L \cdot T \approx 4.2 \times 10^{19}$$

1167Rater inference over the entire 627B-token dataset1168consumes:

1169 FLOPs<sub>infer</sub>  $\approx 6 \cdot 627 \times 10^9 \cdot d^2 \cdot L \approx 8.13 \times 10^{20}$ 

1170

1171

1177

1178

1179

1180

1181

1182

1166

 $FLOPs_{total} \approx 8.17 \times 10^{20}$ 

1172QuRating (Mix of Criteria). Integrating four1173QuRating raters (each covering a distinct aspect)1174requires four forward passes across the full dataset.1175Since retraining is not needed, total cost is:

1176 
$$FLOPs_{mix} \approx 4 \times FLOPs_{infer} \approx 3.26 \times 10^{21}$$

**FIRE.** FIRE uses the same four QuRating raters as input, and hence shares the same inference cost. In addition, it estimates the win-rate-percentile mapping using only 20K pairwise comparisons per rater. The additional cost of this step is negligible compared to inference over 627B tokens.

# 1183 D.4 Integration of Other Raters

FIRE has extremely high scalability: our approach 1184 is not directly related to the specific attributes of 1185 the raters. Therefore, as long as the raters can 1186 provide ratings for the samples and are not com-1187 pletely related to each other, they can be integrated 1188 using the FIRE method. We also attempt to in-1189 tegrate another raters: QuRating(Required Exper-1190 tise), QuRating(Facts and Trivia), DSIR-Book, and 1191 1192 DSIR-Wiki. Tabel 7 shows that the average performance of FIRE, after integrating these four raters, 1193 is better than each individual rater and the Random 1194 baseline, indicating that our integration method is 1195 still effective on other raters. 1196

### **D.5** Prompt for Multi-dimension Analysis

| Prompts for GPT-40 evaluation   |
|---|
| You are a data annotation expert. You should judge that {condition}   |
| Aspects that should NOT influence your<br>judgement:<br>1. Which language the text is written in<br>2. The length of the text<br>3. The order in which the texts are<br>presented   |
| Note that the texts are cut off, so you have<br>to infer their contexts.<br>Here is the text:<br>[TEXT BEGIN]<br>{text}<br>[TEXT END]   |
| Please follow the question order to<br>respond. For answer, only respond yes or<br>no.<br>Return the results for each question in the<br>following json format:<br>[{<br>"quesion": "Is this text has a polished and<br>beautiful writing style ?",<br>"reason": "Fill in the reason for the<br>judgment here",<br>"answer": "yes/no" |
| },<br>]   |

We instruct the GPT-40 to evaluate the data selected through the raters, and here we show the prompts. For dimension, we consider four individual dimensions, the same as QuRating Wettig et al. (2024); and a comprehensive dimension:

- Does this text have a polished and beautiful writing style?
- Does this text contain many facts and trivia? Prefer specific facts and obscure trivia over more common knowledge.
- Does this text have much educational value? 1209
   E.g., it includes clear explanations, step-bystep reasoning, or questions and answers. 1211

# **E** Further Analysis of Experiments

### E.1 Results of different combinations

We present the results of different rater combinations in Table 8. The average scores of FIRE (W.S.+R.E.+F.T.) and FIRE (W.S.+R.E.+E.V.) both surpass the results obtained from combining any two of their individual raters. Furthermore, FIRE (W.S.+R.E.+F.T.+E.V.) achieves even better performance.

#### E.2 Prompt merge effect

We investigate whether combining multiple rules within a single prompt can effectively meet the evaluation standards of each rule. We randomly selected 3,000 data points and guided GPT-4's evaluation using a prompt that integrates multiple rules, alongside conducting individual rule-guided evaluations and separate human annotator evaluations for each criterion. To understand how GPT-4's holistic evaluation aligns with each individual dimension, we employed CoT (Wei et al., 2022) approach: the model first evaluates each rule separately, and then provides an overall evaluation. Each rule is assessed with a binary yes/no question, and after six evaluations, we average the results to obtain the final score (for human evaluations, this entails averaging the scores given by six annotators).

Table 9 displays the percentage of data with a relatively high degree in each dimension, along with

Figure 10: Ablation experiments evaluating the impact of different orthogonality functions on model performance.

the correlation coefficients between GPT-4's and human evaluations. From the proportions of highquality data in each dimension, it is evident that GPT-4's scores approximate human scores more closely when evaluated individually, with differences within a margin of 0.2 at most. However, GPT-4's scores exhibit greater variability when multiple rules are integrated. In terms of correlation coefficients, there is a strong correlation between GPT-4's individual scoring and human scoring, but this correlation significantly diminishes when it comes to comprehensive scoring. Particularly, in the 'Require Expertise' aspect, the correlation is only 0.32. This suggests that GPT-4's current capability to adhere to all rules in a single prompt is still inadequate.

### E.3 Orthogonality Function

There are various methods to calculate orthogonal-1266 ity, and we aim to identify the most effective one. 1267 We compare three functions for orthogonality cal-1268 culation: linear, gaussian, and sym. gaussian (the 1269 symmetrically processed gaussian function). As 1270 illustrated in Figure 10, the three functions achieve 1271 comparable results, all surpassing the configuration 1272 without orthogonality, which demonstrates the ef-1273 fectiveness of incorporating orthogonality. Besides, 1274 the sym. gaussian function outperforms the other 1275 two. The gaussian function smooths the correla-1276

Table 9: Results of GPT-4 and human annotation for 3,000 samples. Sing. = Single, Comp. = Comprehensive.

tion coefficient around zero, while the sym. gaussian function amplifies changes in orthogonality near zero. The linear function, however, strikes a balance between these two. Our experimental results confirm that enhancing the rate of change around zero is more efficient, emphasizing the role of highly orthogonal raters, and intensifying the penalties for raters with high correlation.

### E.4 Effect of Sample/top-K

1296

Qurating (Wettig et al., 2024) suggest that sampling is more effective than directly selecting the top-K data. In this experiment, we integrate four different raters to rigorously investigate the impact of sampling on the model's final performance. Specifically, we calculate the sampling probability for all rated samples using the following softmax formula:

$$P(x) = \frac{exp(I(x)/\tau)}{\sum exp(I(x)/\tau)}$$
(15)

where  $\tau$  is the temperature parameter. We train a model of the same size as in the previous experiments. From the results presented in Figure 11,

Figure 11: The impact of the sample temperature coefficient on model performance.  $\tau$  is the temperature coefficient, and when  $\tau = 0$ , it refers to top-K selection.

several key observations can be made:

(1) Our findings reveal that direct top-K selection outperforms sampling, further affirming the efficacy of our integration method. Additionally, Wettig et al. (2024) posits that sampling enhances data diversity, which is beneficial for model learning. Our results indicate that the top-K scores are higher than the sampling scores, demonstrating that the top-ranked data according to our integration rating exhibit a broader distribution rather than being concentrated in a single domain.

(2) Contrary to the optimal value of 2 suggested by Wettig et al. (2024), our analysis indicates that a relatively smaller  $\tau$  value yields optimal results. A smaller  $\tau$  accentuates the impact of ratings, suggesting that our method effectively selects higherquality data. Furthermore, our multi-dimensional approach also accounts for the diversity of data
