AN ADAPTIVE DEFENSE AGAINST ADVERSARIAL PATCH ATTACKS FOR VISION TRANSFORMERS

Anonymous authors

Paper under double-blind review

ABSTRACT

Vision Transformers (ViTs) have become the prominent architecture for various computer vision tasks due to their superior ability to capture long-range dependencies through the self-attention mechanism. However, recent research indicates that ViTs are highly susceptible to carefully crafted adversarial patch attacks, presenting a significant challenge for practical deployment, particularly in security-critical applications. Existing approaches towards robust ViT frameworks often sacrifice clean accuracy and/or achieve suboptimal robustness, likely due to their uniform handling of diverse input samples. In this paper, we present *NeighborViT*, a novel adaptive defense framework specifically designed to counter adversarial patch attacks for ViTs. NeighborViT stands out by detecting and categorizing different types of attacks on inputs and applying adaptive, tailored defense mechanisms for each type of attack. To realize effective attack detection, categorization, and mitigation, NeighborViT explores the information in neighbor patches of the target patch and strategically employs them for defense. Our experimental results on the ImageNet dataset using various stateof-the-art ViT models demonstrate that NeighborViT significantly enhances robust accuracy without compromising clean accuracy. Our code is available at https://anonymous.4open.science/r/NeighborViT-8255.

1 INTRODUCTION

032 Vision Transformers (ViTs) (Dosovitskiy et al., 2021) have become the leading architecture in var-033 ious computer vision tasks, such as image classification (Zhu et al., 2023), segmentation (Ye et al., 034 2019), and generation (Chen et al.). However, they recently show heightened vulnerability to adver-035 sarial patch attacks (Brown et al., 2017; Gu et al., 2022; Fu et al., 2022; Lovisotto et al., 2022; Yuan et al., 2024). These attacks, which introduce small but strategically placed patches to an image, 037 exploit ViTs' attention mechanism, leading to significant model misclassifications. For example, 038 only 0.5% modifications to the input image can degrade the model's performance to 0% (Lovisotto et al., 2022). This vulnerability underscores a fundamental weakness in the current design of ViTs and raises concerns regarding their reliability in real-world applications. 040

041 Various works have been proposed to enhance the robustness of ViTs. One line of work treats the 042 model as a black box and analyzes the model inputs/outputs to mitigate adversarial patch attacks (Xi-043 ang et al., 2022; Tarchoun et al., 2023; Yang et al., 2024). In contrast, another line of work leverages 044 the unique self-attention mechanism in ViTs to limit the impact of abnormal attention of adversarial patches (Yu et al., 2023; Liu et al., 2023; Mu & Wagner, 2021). Despite their effectiveness, many of the above studies (Yu et al., 2023; Liu et al., 2023; Kim et al., 2023) process clean and malicious 046 inputs indistinguishably, which inevitably harms the model's clean accuracy. Although some stud-047 ies (Xiang et al., 2022; Tarchoun et al., 2023; Yang et al., 2024) can discern adversarial inputs, they 048 rely on computationally expensive detectors to manage the challenges posed by unknown attack sizes and positions, and they treat all adversarial inputs equally without considering the impact of different attacked locations, resulting in limited improvements in robustness. 051

In this paper, we highlight the importance of distinguishing different types of inputs and intro duce *NeighborViT*, an input-adaptive defense framework for ViTs against adversarial patch attacks. NeighborViT not only detects adversarial inputs from clean ones but also categorizes different at-

054 tack types, subsequently adopting tailored defense strategies. The key insight behind NeighborViT is leveraging information from neighboring patches of target patches for effective attack detection, 056 categorization, and mitigation. Specifically, adversarial patches typically exhibit high pixel dis-057 continuity compared to clean patches. By analyzing pixel-level discontinuity differences between 058 target and neighboring patches, we develop a lightweight and accurate algorithm to detect and locate attacks. Such detection enables us to maintain the target models' clean accuracy. To improve robustness, we also distinguish between *catastrophic* and *non-catastrophic attacks* based on whether they 060 occur in essential or non-essential areas for classification. The categorization is achieved by replac-061 ing the adversarial patch with its neighbors and observing model output variations. Non-catastrophic 062 attacks show more consistent outputs since they do not harm the essential features for classification. 063

064 After categorization, we develop specialized defenses for different types of attacks. For noncatastrophic attacks, we replace adversarial patches with neighboring patches, which entirely remove 065 adversarial information and preserve the essential feature for classification. Such replacement can-066 not be applied to catastrophic attacks, as this would result in the loss of essential features. Hence, we 067 design a fine-grained attention suppression mechanism instead to suppress the adversarial attention. 068

- 069 Our contributions are summarized as follows:
 - We develop NeighborViT, a novel robust ViT framework that protects ViT against adversarial patch attacks. We utilize neighbor information to categorize model inputs and design tailored defenses for each category. This adaptive defense strategy enables us to achieve high robustness while maintaining clean accuracy.
 - We explore the pixel-level discontinuity differences between adversarial patches and the neighboring patches and present a model-agnostic attack detector. Our detector can accurately and efficiently detect and localize adversarial patches of unknown sizes.
 - We show the necessity to differentiate between catastrophic and non-catastrophic attacks and propose an essential/non-essential area detector for this. The detection is enabled by exploiting model prediction variations when adversarial patches are replaced with different neighboring patches.
 - We propose a fine-grained attention suppression algorithm for catastrophic attacks and an adversarial patch reconstruction method for non-catastrophic attacks. These tailored defenses enable optimized robust accuracies.

To evaluate our method, we conduct extensive experiments on 12 representative ViT models across various state-of-the-art attack approaches. Our results show that we achieve the best robust performance while maintaining clean accuracy compared to other methods.

2 **BACKGROUND & RELATED WORKS**

Vision Transformer: The Vision Transformer (ViT) (Dosovitskiy et al., 2021), inspired by NLP 092 models like BERT (Devlin et al., 2019), introduces self-attention to image classification, offering an alternative to traditional CNNs. ViTs excel in tasks requiring broader context understanding, as 094 they avoid CNNs' reliance on local receptive fields. Notable ViT models include ViT (Dosovitskiy et al., 2021), DeiT (Touvron et al., 2021), BiFormer (BiF) (Zhu et al., 2023), and TransNeXt 096 (TNX) (Shi, 2024), with TNX and BiF outperforming CNNs by over 15% in classification tasks. A typical workflow of ViTs is as follows. ViTs split input images into patches, transforming them 098 into embeddings. These embeddings, along with positional encodings, are fed into a transformer 099 encoder composed of multiple transformer blocks. In each block, embeddings first pass through the Multi-Head Self Attention (MHSA) layer, where they are converted into queries (Q), keys (K), and 100 values (V). Subsequently, the attention output for each head is calculated as

101 102 103

104

Attention
$$(Q, K, V) = \operatorname{softmax}\left(\frac{QK^T}{\sqrt{d_k}}\right)V$$
 (1)

105 where d_k is the vector dimension. After that, the outputs from all attention heads are concatenated and linearly transformed, producing the output of the MHSA layer. The output is then passed 106 through residual connections and layer normalization before being fed into the MLP layer to in-107 corporate nonlinear information. Through layer-by-layer connections, the final classification is achieved through an MLP head using the representation of a unique CLS token. This structured approach enables ViTs to effectively leverage self-attention for superior classification performance.

Adversarial patch attacks: Brown et al. (Brown et al., 2017) first introduce adversarial patch 111 attacks, which limit the attack region to a patch area. In Appendix A.1, we show some examples 112 of patch attacks. Initially targeting CNNs, adversarial patch attacks have now expanded to Vision 113 Transformers (ViTs). Recent studies (Gu et al., 2022; Fu et al., 2022) reveal ViTs' vulnerability to 114 patch attacks, exploiting ViTs' need to partition images into patches for attention computation. One 115 line of ViT's patch attack focuses on designing loss functions that target only the model's output, 116 utilizing gradient to optimize the adversarial patch aligned with the input patches of ViTs, such as 117 Token-attack (Joshi et al., 2021) and ViTRPP (Gu et al., 2022). Based on the global reasoning 118 of attention being the source of the vulnerability of ViT to patch attacks, another line of work not only utilizes the model's output but also incorporates attention-aware loss. Fu et al. propose (Fu 119 et al., 2022) Patch-Fool with integrated attention-aware patch selection technique and attention-120 aware loss design. Subsequently, Lovisotto et al. (Lovisotto et al., 2022) observe that using post-121 softmax attention scores as a loss in Patch-Fool leads to the issue of smaller gradients, thus limiting 122 the attack's potential. Therefore, they proposed Attention-fool, which designs the loss using pre-123 softmax attention scores to avoid this problem. 124

Defense methods for ViTs: Defense strategies against ViT's patch attacks can be divided into 125 model-agnostic and ViT-specific methods. Model-agnostic defenses treat the model as a black box 126 and are generally applicable to both CNNs and ViTs; for instance, PatchCleanser (Xiang et al., 127 2022) uses two rounds of moving window masking and output analyzing to get the correct answer; 128 Jedi (Tarchoun et al., 2023) identifies adversarial patches using entropy analysis and an autoencoder, 129 exploit the fact that adversarial patches have higher entropy than natural images. To get the correct 130 classification result, Jedi applies a pixel reconstruction method on attacked images. ViT-specific 131 defenses leverage attention mechanisms; for example, Robust Self-Attention Layer (Mu & Wagner, 132 2021) detects and masks outlier tokens based on their value vector; ARMRO (Liu et al., 2023) 133 detects and masks adversarial patches by identifying the layers where the adversarial token's score 134 becomes most prominent, based on its varying behavior across different layers; RTA (Yu et al., 135 2023) addresses the issue of adversarial patches attracting excessive attention in ViTs by applying a restriction operation on the attention matrix. 136

However, most existing methods do not differentiate between clean and adversarial inputs, limiting their robustness and clean accuracy. Even when adversarial patch attacks are identified in some methods, they do not classify the types of attacks (e.g., catastrophic and non-catastrophic attacks), limiting their robustness. In contrast, our approach adaptively processes different kinds of input, resulting in an improved model's clean accuracy and robustness. The necessity of adaptive processing is elaborated further in the following section.

- 143
- 144 145

3 DESIGN OF NEIGHBORVIT

146 147

In Fig. 1 Top, we introduce our adaptive defense framework, named NeighborViT, which distin-148 guishes different types of adversarial patch attacks and adopts corresponding defense methods. The 149 framework comprises an attack detector, an essential/non-essential area detector, image reconstruc-150 tion for non-catastrophic attacks, and attention suppression for catastrophic attacks. The catastrophic 151 attacks represent the attacks occurred in the essential areas and non-catastrophic attacks represent 152 the attacks located in the non-essential areas. For any input sample, we first conduct attack detec-153 tion through the lightweight and effective attack detector (detection). If the input is clean, it will 154 be directly inputted into the ViT model for classification. Conversely, if the input contains adver-155 sarial patches, we use the essential/non-essential area detector to identify whether the attack occurs 156 in the essential area or non-essential area (categorization). After that, we design different defense 157 methods to mitigate the impact of adversarial patches (mitigation). If the attack is located in the 158 essential area, we use fine-grained attention suppression to defend catastrophic attacks. If it occurs 159 in the non-essential area, we remove the adversarial patches and reconstruct the image. Notably, all the above process, *i.e.*, detection, categorization, and mitigation, are enhanced with the information 160 explored in the neighbors of target patches. With this framework, we can achieve superior robust 161 performance against adversarial patch attacks while maintaining clean accuracy.

Figure 1: **Overview of NeighborViT**. *Top*: The framework of NeighborViT. Each input sample is categorized into clean samples, catastrophic attacks, and non-catastrophic attacks by the attack detector and essential/non-essential area detector. We do not modify clean inputs and adopt different defense methods (e.g., reconstruction or attention suppression mechanisms TAS) for different attack types. *Middle*: The details of the attack detector, which divides the input samples into clean samples and adversarial patch attacks. *Bottom*: The details of the essential/non-essential area detector, which distinguishes whether the attack occurs in essential areas (i.e., catastrophic attacks) or non-essential areas (i.e., non-catastrophic attacks). We add red boxes on the images for better visualization.

3.1 ATTACK DETECTOR

192

193

194 Why do we need to design a novel attack detector? The answer lies in two aspects. On the one 195 hand, in existing research of enhancing the robustness of ViTs, some methods (Yu et al., 2023; Liu 196 et al., 2023; Kim et al., 2023) overlook whether an attack has occurred and treat all the input sam-197 ples equally, which often compromises the clean accuracy of the target model. On the other hand, although other approaches (Xiang et al., 2022; Yang et al., 2023; Tarchoun et al., 2023) consider 199 to detect adversarial patches, they either need to train an auxiliary model or query the target model 200 multiple times to deal with the challenges posed by unknown adversarial patch size and location, 201 leading to significant costs. In this paper, we present a lightweight attack detector that can accurately detect adversarial patches of unknown locations and sizes. 202

203 Our motivation stems from the low pixel continuity inside adversarial patches. The generation pro-204 cess of the adversarial patches neglects the relationships between pixels and results in a noticeable 205 pixel gradient. This gradient can be detected through traditional image processing tools (Sobel et al., 206 1968; Prewitt et al., 1970; Canny, 1986). In particular, the sobel operator (Sobel et al., 1968), designed for edge detection, utilizes horizontal and vertical kernels to detect pixel variations in both 207 directions and effectively highlights pixels with high gradients. Meanwhile, the pixels inside adver-208 sarial patches also have high gradients that can be detected by the operator. We present an example 209 to show the effect of the sobel operator on adversarial patches in Fig. 1 *Middle* (more examples can 210 be seen in Appendix A.2), where the white areas represent higher sobel scores. It indicates that the 211 adversarial patches show the most salient gradient, while the pixel gradients within clean patches 212 are comparatively smaller. This contrast can be used for adversarial patch detection. 213

To detect and locate adversarial patches, we first use the above sobel operator to get the sobel score of each pixel and calculate average sobel score of pixels in each patch, denoted as *AvgSobel*. The patch with a high average sobel score is likely to be an adversarial patch. However, some clean patches also exhibit relatively high AvgSobel values, relying exclusively on the AvgSobel score for detection and localization may lead to wrong results. To address this, we introduce a new distance score d that not only considers the AvgSobel of the current patch but also incorporates the AvgSobelof patches inside neighbor patches, denoted as $AvgSobel_{n_k}$, where the n_k represents the neighbor patches. The distances d of all patches are combined. The computation of d is illustrated in Eq. 2 and K represents the number of the sampled neighbor patches.

$$d = AvgSobel - \frac{\sum_{k=1}^{K} AvgSobel_{n_k}}{K}$$
(2)

$$d_{max} = \max_{d_z \in \mathbf{D}} \{d_1, d_2, \cdots d_i, \cdots, d_z\}$$
(3)

Since the location of the adversarial patches is unknown, we propose a sliding window method to scan for suspicious patches across the image. First, we assume that the sliding window size and attack patch size are equal to the model's input patch size. For the i_{th} slide, we sample the neighbors of current window and calculate the above distance d_i . We group all d into vector **D**. Second, when finishing the window sliding process, we get the maximum distance d_{max} through Eq. 3, where z represents the total number of slides. At last, if the maximum distance d_{max} exceeds the threshold ε , we deem that we have detected and located the adversarial patches and can obtain the mask **M** of the adversarial patches; otherwise, the input sample is clean.

234 However, in practice, the size of the adversarial patches is often inconsistent with the input patch size 235 of the model, and their sizes are unknown. To accurately locate the adversarial patches, we introduce 236 a dynamic window size strategy during the window sliding process(Fig. 1 Middle). We start with a 237 large window size and conduct one round of sliding for each window size. In this case, we calculate 238 the mean of all pixel gradients within the variable window. If no adversarial patch is detected in 239 the current sliding round, we gradually reduce the window size and continue to the next slide. If 240 no adversarial patch is detected after the last round of sliding (i.e., window size equals to the input patch size of the model), we deem that the input sample is clean. The detailed detection algorithm 241 is provided in Appendix A.4. Notably, our attack detector does not require to train auxiliary models 242 or query the target model, thereby incurring no additional cost. 243

3.2 ESSENTIAL/NON-ESSENTIAL AREA DETECTOR

Current defense studies (Yu et al., 2023; Tarchoun 247 et al., 2023; Liu et al., 2023) often do not distin-248 guish different types of adversarial patch attacks 249 and treat them equally. However, we need to utilize 250 different defense measures to achieve better robust 251 performance. Specifically, if the attack occurs in 252 the non-essential areas (non-catastrophic attacks), 253 which does not contain essential features for model classification, we can completely remove these at-254 tacked information to achieve strong robust perfor-255 mance of the model. To demonstrate this, we com-256 pare the effect of the two methods (i.e. remove ad-257 versarial patches and RTA (Yu et al., 2023)) when 258 attacks are located in the non-essential areas, where 259 RTA uses global attention for attention suppres-260 sion, which is a typical method that still retains the 261 attack information. Specifically, we select four rep-

Table 1: Distinguishing different types of adversarial patch attacks is important (robust accuracy (%) for attacks located in essential and non-essential areas is reported. *Left*: attacks located in non-essential areas; *Right*: attacks located in essential areas).

<sup>resentative ViT models and 1,500 non-catastrophic attacks generated by Patch-Fool (Fu et al., 2022).
We set the attack patch size to twice the model's input patch size. The results in Table 1</sup> *Left* show that removing adversarial patches achieves better robustness, suggesting that removal is a superior defense for non-catastrophic attacks.

Is it appropriate to completely remove adversarial patches if they are located in essential areas?
To answer this question, we conduct an experiment to compare the effect of the two methods *i.e.*, remove adversarial patches and RTA, when attacks are located in the essential areas. Specifically, we select 1,500 catastrophic attacks generated by Patch-Fool, and the other experimental settings are the same as those in the non-catastrophic attacks experiment. The results in Table 1 *right* are

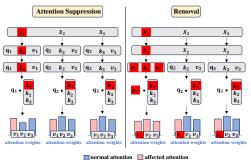

270 different from those of non-catastrophic attacks 271 and show that attention suppression achieves better 272 robustness. To explore the reason, we visualize the 273 attention difference between these two methods in 274 Fig. 2. Current attack methods (Fu et al., 2022; Lovisotto et al., 2022) often amplify the key vectors to 275 achieve better attack performance, and red squares 276 in Fig. 2 Left represent the attacked token. The suppression method only suppresses the key vec-278 tors of adversarial patches while maintaining q and 279 v vectors, leading to less impact on the attention 280 calculation process. In contrast, as shown in Fig. 2 281 Right, removing the adversarial token also affects 282 the query and value vectors and has a greater im-283 pact on attention calculation (the red squares repre-284 sent the affected vectors). This phenomenon is also 285 verified in Appendix A.3, which shows the impact of these two methods on the attention map. The 286

302

306

307

Figure 2: The effect of attention suppression and removal for attacks occurred in essential areas on the attention mechanism. X_1 denotes the adversarial token and X_2 , X_3 are clean tokens. *Left*: suppress the attention of X_1 ; *Right*: remove token X_1 .

above experimental results and analysis suggest that adversarial patches have useful information for 287 classification and cannot be completely removed for catastrophic attacks. 288

289 Based on the above experimental results and analysis, we need to distinguish essential and non-290 essential areas. To effectively distinguish them, we propose a lightweight essential/non-essential 291 area detector (ENED) (Fig. 1 Bottom). The losses of non-essential features do not impact the model's predictions, whereas removing essential features causes the predictions unreliable. This 292 difference allow us to determine whether the attacked area is essential or non-essential by observing 293 the model's output . Specifically, after the attack detector, we obtain the mask \mathbf{M} of adversarial patches, with which we can use k neighbors of the adversarial patches to reconstruct k images. 295 After that, we input the reconstructed images into the model to obtain the corresponding output 296 probabilities. At last, we compute the average similarity between each pair of outputs (Eq. 4), 297

$$\overline{similarity_{out}} = \frac{\sum_{i,j}^{k} sim(exp(out_i), exp(out_j))}{\binom{k}{2}} \qquad i, j = 1 \cdots \binom{k}{2}, i < j \qquad (4)$$

where out_i , out_i refers to the output of the model for two different reconstructed images. When the average similarity $similarity_{out}$ is below the predefined threshold γ , we deem that the attacked 303 area is an essential area; otherwise, the attack occurs in the non-essential area. The ENED detection 304 algorithm is shown in Appendix A.4. 305

3.3 ADAPTIVE DEFENSE FOR DIFFERENT ATTACK CATEGORIES

308 After we categorize adversarial patch attacks, we introduce corresponding defense methods for dif-309 ferent types of attacks. We introduce these two different strategies below.

310 Defense for non-catastrophic attacks (Reconstruction). As mentioned above, removing adver-311 sarial patches is a superior defense for attacks occurred in non-essential areas. Specifically, utilizing 312 the mask \mathbf{M} (locating the adversarial patches), we can calculate the mask of neighbor patches (lo-313 cating neighbor patches). After that, we randomly select a neighbor patch and use it to fill the 314 masked adversarial patches, through which we get a reconstructed image. Eventually, we feed the reconstructed image into the original ViT architecture to obtain the final prediction. 315

316 Defense for catastrophic attacks (TAS). As mentioned in the Section 3.2, attention suppression 317 method, like RTA (Yu et al., 2023), is an effective approach for attacks occurred in essential areas. 318 Specifically, RTA restricts the attention of each token with unified global attention (i.e., mean of all 319 token attention weights) to prevent the model from being misled by adversarial patches. However, 320 calculating the mean of all token attentions is inevitably affected by the adversarial patches, making 321 it difficult to effectively suppress the attention weights of adversarial tokens. Moreover, since some research (Vaswani, 2017; Han et al., 2022) has demonstrated that different attention heads stand 322 for different representation subspaces, using a unified global attention for all heads is suboptimal for 323 attention suppression. To solve the first problem, we remove the adversarial tokens when calculating

Table 2: Comparison of different defense methods. We report the model's average clean accuracy
 and robust accuracy (%) across various sizes of attack patches. The results demonstrate that our
 method has achieved exceptional robust performance under a range of attacks. The best results for
 each attack are marked in bold, and the second best are underlined.

the mean values of attention weights to suppress the attention weights of adversarial tokens more effectively. To deal with the second problem, we compute the mean values of attention weights separately for each head. The resulting attention suppression method is illustrated by Eq. 5,

$$TAS(\mathbf{A}_{i,j,h}^{(m)}) = \frac{\mathbf{A}_{i,j,h}^{(m)}}{\mathbf{A}_{j,h}^{(m)}} min(\mathbf{A}_{j,h}^{(m)}, \alpha \overline{\mathbf{A}_{mask_{h}}^{(m)}})$$
$$\frac{1}{\mathbf{A}_{mask_{h}}^{(m)}} = \frac{1}{N^{2} - win_{adv}^{2}} \sum_{i,j} \mathbf{A}_{i,j,h}^{(m)}, (i,j) \neq p_{adv}$$
(5)

where we denote $\mathbf{A}^{(m)}$ as the attention weight of the m_{th} block of the ViTs. The *i*, *j* represent the index of attention values and *h* is the index of different heads. The $\mathbf{A}_{j,h}^{(m)} = \frac{1}{N} \sum i \mathbf{A}_{i,j,h}^{(m)}$ represents the average attention contribution of the j_{th} token and α represents the suppression coefficient. We denote the average attention weight of clean tokens as $\overline{\mathbf{A}_{mask_h}^{(m)}}$, where *N* denotes the total number of patches. The win_{adv} is the attack patch size and p_{adv} is the index of adversarial patches detected by the attack detector (can be found in Appendix A.4).

4 EXPERIMENTAL EVALUATION

4.1 Setup

364 Models and Datasets. In our experiments, the target models we select are from the ViT family 365 (ViT-S, ViT-B, and ViT-L) (Dosovitskiy et al., 2021), the DeiT family (DeiT-T, DeiT-S, and DeiT-366 B) (Touvron et al., 2021), the BiFormer family (BiFormer-T, BiFormer-S, and BiFormer-B) (Zhu 367 et al., 2023), and the most recent TransNeXt family (TransNeXt-T, TransNeXt-S, and TransNeXt-368 B) (Shi, 2024). We utilize the official pre-trained versions of all selected models, employing an 369 input patch size of 16×16 pixels. To generate adversarial patch attacks, we utilize the validation set of ImageNet (Deng et al., 2009) as the clean image dataset and then apply various attack strategies 370 under different ViTs on these clean images. We set a wide range for the attack patch size, ranging 371 from 0.5% to 8% of the total pixel area of the image. Specifically, we define attack patch size = 372 $1 \times 2 \times 3 \times 4 \times$, representing that the side length of the attack patches is 1, 2, 3, and 4 times the 373 input patch length (e.g., $2 \times$ represents an attack patch size of 32×32 pixels). 374

Attack Strategies. To demonstrate the effectiveness of our method, we employ multiple state-ofthe-art attack methods in our experiment, including 1) ViTRPP (Gu et al., 2022), 2) Patch-Fool (Fu
et al., 2022), and 3) Attention-Fool (Lovisotto et al., 2022). As all these methods are white-box attacks, they represent the most powerful ViT attack strategies currently available. The parameter

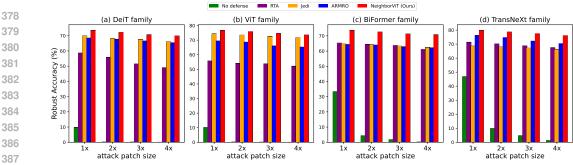

Figure 3: Average robust accuracy (%) of different model families under various sizes of adversarial patches. Each value is averaged across all models within each ViT family. attack patch size = $1 \times , 2 \times , 3 \times , 4 \times$ denotes that the side length of the attack patch is 1, 2, 3, and 4 times the input patch length of the target model.

settings for all these attack strategies are identical to those in their original papers. The detailed attack settings are presented in Appendix A.5.

Baseline Defense Methods. In our experiments, we compare our method with several representative robust ViT frameworks, including RTA (Yu et al., 2023), ARMRO (Liu et al., 2023), and Jedi (Tarchoun et al., 2023), of which ARMRO and Jedi are the current state-of-the-art defense approaches. The detailed configurations of these baseline defense methods are presented in Appendix A.6.

Evaluation Metrics. To evaluate our proposed framework, we employ two metrics to assess its per formance: 1) *Clean Accuracy*: This metric measures the percentage of correctly classified images
 within the clean image dataset that has not been modified by any attacker. 2) *Robust Accuracy*: This
 metric assesses the model's resilience to adversarial attacks. It measures the percentage of correctly
 classified images under adversarial patch attacks.

4.2 COMPARISON OF DIFFERENT DEFENSE METHODS

In this section, we comprehensively compare our defense method with RTA, Jedi, and ARMRO. We
first randomly select 5,000 clean images from the validation set of Imagenet to evaluate the defended
ViTs' clean accuracy. As shown in Table 2, our method achieves the highest clean accuracy, with an
average reduction of less than 0.1% compared to the original model. This marks a significant improvement over Jedi, which has the smallest reduction among the previous methods, with a decrease
of 0.8%. The superior performance of our framework is attributed to its differentiated handling of
clean samples and adversarial patch attacks, and the high effectiveness of the attack detector.

413 Next, we assess the robust accuracy of the defended ViTs on adversarial images generated using 414 various patch attack methods under multiple attack patch sizes. Table 2 presents different models' 415 average robust accuracy across various attack patch sizes for each attack strategy. Meanwhile, Fig. 3 illustrates the average robust accuracy of different model families under various sizes of adversarial 416 patches. As shown in Fig. 2 and Tab. 3, our method consistently outperforms others across all ViT 417 models, attack methods, and attack patch size values, demonstrating its effectiveness in countering 418 adversarial patch attacks. This success can be attributed to our adaptive defensive strategies against 419 different types of adversarial attacks (catastrophic attacks and non-catastrophic attacks). Notably, 420 our approach shows more significant improvement in defense against Patch-Fool and Attention-Fool 421 compared to ViTRPP. This is because the adversarial patches generated by the former two strategies 422 are more evenly distributed across essential and non-essential areas. When a specific type of attack 423 dominates, the performance of our framework converges to that of a single defense method (e.g., 424 when all attacks are catastrophic, the performance of our framework is comparable to that of RTA). 425 In such cases, the improvement provided by our adaptive defense mechanism becomes limited. In 426 real-world scenarios, since it is uncertain whether the input patch attack will be catastrophic or 427 non-catastrophic, only our adaptive method can consistently achieve effective defense.

428 429

- 4.3 EVALUATION OF THE KEY COMPONENTS OF NEIGHBORVIT
- 431 In this section, we evaluate the effectiveness of the key components (attack detector, essential/nonessential area detector, and token attention suppression) in our defense framework.

Effectiveness of the Attack Detector. The at-447 tack detection strategies used in current ViTs de-448 fense methods either need to train an auxiliary 449 model (Tarchoun et al., 2023) or query the target 450 model multiple times (Xiang et al., 2022; Yang 451 et al., 2023), both of which are computationally ex-452 pensive. In contrast, our attack detector is more 453 accurate and lightweight. To demonstrate this, 454 we compare the detection methods proposed in 455 PatchCleanser (Xiang et al., 2022), IBCD (Yang et al., 2023), and Jedi (Tarchoun et al., 2023) with 456 ours, evaluating both detection accuracy and aver-457 age time cost for each sample. For the test dataset, 458 we select a mixture of 500 clean and 500 adver-459 sarial patch attacks generated with Attention-Fool 460

toward DeiT-X. As shown in Fig. 4, our attack detector achieves the highest detection accuracy 461 across various attack patch sizes (with improvements of 10% to 12%) while keeping the time cost 462 among the lowest. Additionally, as the attack patch size decreases, the time cost increases due to the 463 search process starting from larger patches and progressively narrowing to smaller ones. 464

Necessity and Efficacy of the Essential/Non-Essential Area Detector. To demonstrate the ne-465 cessity and efficacy of our essential/non-essential area detector (ENED), we conduct experiments 466 comparing three defense strategies: 1) TAS Only, where adversarial examples bypass ENED and 467 are handled solely by the token attention suppression method; 2) NR Only, where adversarial exam-468 ples bypass ENED and are processed using the neighbor replacement method; and 3) Both, where 469 ENED categorizes adversarial patch attacks into catastrophic attacks and non-catastrophic attacks, 470 subsequently handling them with TAS and NR, respectively. For the test dataset, we select one 471 model from each ViT family and perform different attack strategies with two attack patch sizes. We then apply the three defense strategies to the target models and evaluate the robust accuracy of the 472 models. As shown in Table 3, models with activated ENED achieve the highest robust performance, 473 validating the efficiency and necessity of ENED. 474

475 Effectiveness of Token Attention Suppression. To enhance the robustness of ViT against catas-476 trophic attacks, we propose token attention suppression (TAS), which applies fine-grained token 477 attention suppression using masked global token information (attention of non-attacked patches). In this section, we assess the impact of different attention suppression strategies' influence on the 478 robust accuracy of the defended models. We compare three approaches: no attention processing, 479 RTA's restriction method, and our TAS, where we keep the non-catastrophic defense approach the 480 same. As shown in Table 4, TAS achieves the best robust performance, with nearly a 7% improve-481 ment on DeiT-S and approximately a 5% improvement on ViT-S, BiF-S, and TNX-S, highlighting 482 its effectiveness against catastrophic attacks. 483

484

443

444

445

446

486 4.4 Hyper-Parameters

487 488

To evaluate the robustness of our proposed NeighborViT architecture, we conduct comprehensive 489 studies by varying the hyper-parameters within our framework and compare the defensive effective-490 ness with the state-of-the-art method, Jedi. We employ the DeiT-T model architecture as the target 491 model and randomly select 2,500 clean images to generate adversarial patch attacks for validation.

492 **Influence of** ε . We evaluate the de-493 tection threshold ε in our attack detec-494 tor, which determines whether an in-495 put sample is classified as an adver-496 sarial example. For this experiment, 497 we utilize multiple attack strategies with 498 attack patch size = 2. We adjust ε 499 and assess both the clean accuracy and robust accuracy of the defended model. 500 As shown in Table 5, when ε is less 501 than 2.25, our method consistently out-502 performs Jedi in robust accuracy across all attack scenarios. Additionally, for ε 504

Table 5: The impact of different AD thresholds ε on clean accuracy and robust accuracy. We report CA and RA under different attack methods. CA: clean accuracy; RA: robust accuracy. The results of our defense method, which are better than those of Jedi, are marked in bold.

ε		1.95	2.00	2.10	2.15	2.25	2.35	2.45	2.55	Jedi
ViTRPP	CA RA	67.2 70.2	68.4 70.3	71.6 71.1		72.4 68.6		72.4 64.7	72.4 62.8	69.8 68.4

Attention-F	CA RA	68.9 71.6	70.3 71.7	72.4 71.6		72.4 65.3		72.4 60.7	72.4 59.8	70.0 64.7

greater than 2.10, it maintains a clear advantage over Jedi in clean accuracy. When ε is between 505 2.10 and 2.25, our method consistently outperforms Jedi in terms of both clean accuracy and robust 506 accuracy across the three attack scenarios. 507

Influence of γ . We assess the detec-508 tion threshold γ of our essential/non-509 essential area detector for categorizing 510 adversarial inputs. For this experiment, 511 we utilize Patach-Fool as the attack 512 strategy with multiple attack patch sizes. 513 We adjust γ and evaluate the robust ac-514 curacy of the defended model. The re-515 sults are shown in Table 6. Under each

Table 6: The impact of different ENED thresholds γ . The results better than Jedi are marked in bold. $1 \times, \dots, 4 \times$ denotes attack patch size = $1 \times, \dots, 4 \times$.

γ	2.0	2.15	2.25	2.35	2.45	2.55	2.65	Jedi

versarial tokens). In this section, we aim to assess the impact of α . For this experiment, we ultilize 525 Patach-Fool as the attack strategy with attack patch size = 2. We adjust α and assess the robust 526 accuracy of the defended model, with the results shown in Tab. 7. Our approach achieves stronger 527 defense performance than the best baseline Jedi across a wide α range (from 1.00 to 1.30). 528

530 531

529

5 CONCLUSION

532 In this work, we introduce NeighborViT, a novel defense framework for Vision Transformers (ViTs) 533 designed to counter adversarial patch attacks. Unlike traditional defense methods that treat all input 534 samples equally, NeighborViT categorizes different types of inputs and applies adaptive, tailored defense mechanisms. Specifically, NeighborViT employs an attack detector to identify potential 536 attacks in input images and further classifies the detected adversarial examples into catastrophic or non-catastrophic attacks. The key to NeighborViT's ability to detect, categorize, and mitigate adversarial attacks lies in its strategic use of neighbor information at various stages. Experimental 538 results on both classical and state-of-the-art ViTs demonstrate the effectiveness of our proposed method, achieving superior robust performance while maintaining clean accuracy.

A APPENDIX

A.1 ADVERSARIAL PATCH

Figure 5 shows some examples of adversarial patches.

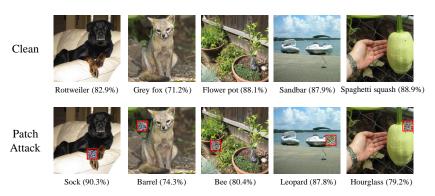

Figure 5: **Examples of patch attacks**. **First row:** Clean samples; **Second row:** Adversarial examples derived from various patch attack methodologies. Adversarial patches are highlighted with red boxes for better visualization.

A.2 ADVERSARIAL PATCH DETECTION WITH SOBEL OPERATOR

Figure 5 shows some examples of adversarial patches detection with sobel operator.

patch attacksobel scoreImage: patch attacksobel scoreImage: patch attacksobel scoreImage: patch attacksobel scoreImage: patch attackImage: patch attack</

 Figure 6: The potential of sobel operator for adversarial patch attack detection. We calculate the gradient of pixels on the image and white areas represent higher sobel scores.

A.3 TAS & REMOVAL FOR CATASTROPHIC ATTACKS

In this section, we visualize the different effects of attention suppression (TAS) and removing adversarial patches on essential area attacks. We still analyze from the perspective of attention. Since the essential features contained in the essential area have been lost, our defense at this time should minimize the focus impact on other essential features. In Fig. 7, we visualize the changes in the attention of each layer for essential area attacks after using *1* neighbor replacement (NR) to reconstruct the

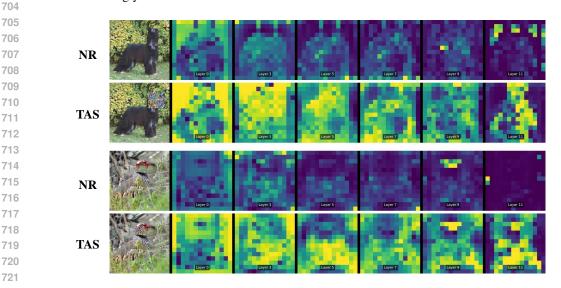

image and 2) using TAS for attention suppression. The selected samples are correctly classified with TAS but wrongly with NR.

Figure 7: Comparison between neighbor replacement construction (NR) and attention suppression with global attention algorithm (TAS). The generation of the adversarial patches mainly changes their key vectors while the changes to the query and value are relatively small. The attention suppression method only suppresses the key vector and affects the attention calculation less; however, directly replacing the original adversarial patches with a neighbor will incur more significant effect on query and value vectors and affect the attention calculation more.

728 729

A.4 ALGORITHMS

731 This section details the algorithmic principles of the attack detector (AD), essential/non-essential 732 area detector (ENED). We have uniformly adopted the neighbor-informed mechanism in the design 733 of these components. What differs is the type of neighbor information we consider in each component. In AD, We summarize our attack detection algorithm in Algorithm 1. For any given input 734 x, we set the initial sliding window size to win_h = win_w = 4, beginning the detection from the 735 top-left region of the image with a window stride equivalent to the model's patch size. After each 736 window slide, we calculate the average sobel score of the patch within the current window. Con-737 currently, we sample neighbors in the four directions-top, bottom, left, and right-with the same 738 size as the current window and compute the average score of all neighboring patches. After that, we 739 calculate the distance of these scores from the current window's patch score. If the current distance 740 exceeds the maximum distance d_{max} updated in the previous instance, we update this calculation 741 as the new maximum distance. Once a round of searching is completed, we obtain the maximum 742 distance for that window size. If this distance surpasses a preset maximum distance ε , we consider 743 the adversarial patches to have been detected and localized effectively and we can obtain the mask 744 M of adversarial patches. Otherwise, we reduce the window size and proceed to the next round of 745 searching. Since our distance measurements are patch-wise, we can design a uniform threshold ε without dynamic variation for each attack methods. 746

747

In essential/non-essential area detection, we refer to the pixels of neighbor regions within the image.
 The implementation details of the algorithms are presented in Algorithm 2.

749 750

751

A.5 ATTACK CONFIGURATIONS

752 We show the attack parameters in Tab. 8. We employ three attack scenarios: ViTRPP, Patch-753 Fool, and Attention-Fool. In each attack scenario, we set the perturbation area size with 754 $attack \ patch \ size = 1 \times, 2 \times, 3 \times, 4 \times$. T-iters represents the total number of iterations. lr rep-755 resents the learning rate for the generation of adversarial patches. #steps and gamma denotes that 756 for every #steps epoch, the learning rate is multiplied by gamma (which is typically less than 1) to

A.6 DEFENSE CONFIGURATIONS

In this section, we will present the detailed parameters of various baseline defense methods and our approach NeighborViT (Tab. 9, Tab. 10). In RTA, α is the restriction parameter. In JeDi, ϵ is the

Table 9:	Baselin	e Defense Par	rameters
	Co	nfigurations	-
	RTA	<i>α</i> =1.15	-
	JeDi	ϵ =18.4;r=5	-

entropy detection limit and r neighbor sampling radius. In ARMRO, τ is the threshold to identify whether adversarial, and Nd is a preset coefficient stating the number of tokens needed to detect. In NeighborViT, ε and γ represent the attack detector (AD) and the essential/non-essential area detector (ENED) detection threshold, respectively. α represents the attention suppression coefficient parameters.
