

Adaptively Robust and Sparse K -means Clustering

Anonymous authors

Paper under double-blind review

Abstract

While K -means is known to be a standard clustering algorithm, its performance may be compromised due to the presence of outliers and high-dimensional noisy variables. This paper proposes adaptively robust and sparse K -means clustering (ARSK) to address these practical limitations of the standard K -means algorithm. We introduce a redundant error component for each observation to enhance robustness, and this additional parameter is penalized using a group sparse penalty. To accommodate the impact of high-dimensional noisy variables, the objective function is modified by incorporating weights and implementing a penalty to control the sparsity of the weight vector. The tuning parameters to control the robustness and sparsity are selected by the Gap statistic. Through simulation experiments and real data analysis, we demonstrate the superiority of the proposed method to existing algorithms in identifying clusters without outliers and informative variables simultaneously.

1 Introduction

Identifying clustering structures is recognized as an important task in pursuing potential heterogeneity in datasets. While there are a variety of clustering methods, K -means clustering (Forgy, 1965) is the most standard clustering algorithm and is widely used in many scientific applications. However, real-world datasets present significant difficulties, such as the presence of outliers and high-dimensional noisy characteristics. Regarding the outlier issues, there are some attempts to robustify the standard K -means, such as trimmed K -means (Cuesta-Albertos et al., 1997) and robust K -means (Klochkov et al., 2021). On the other hand, the existence of high-dimensional noisy characteristics is typically addressed through clustering approaches that emphasize sparsity for variable selection. In particular, Witten & Tibshirani (2010) proposed a lasso-type penalty for the variable weights incorporated in the clustering objective function. However, the effectiveness of this algorithm might be lost if the dataset contains a significant number of outliers. While there are several methods to address either of two aspects (existence of outliers and noisy variables), practically useful methods to address two aspects simultaneously are scarce. One exception is the method proposed by Kondo et al. (2016). However, this approach requires the assumption of a trimming level in advance. In contrast, Brodinová et al. (2019) introduces an approach beginning with eliminating outliers identified by the model. However, this methodology potentially leads to reduced sample size and may result in information loss. Moreover, if the approach learns to handle unusual data by adjusting outliers instead of removing them, it particularly helps to preserve the continuity of estimating parameters.

In addition to clustering methods based on objective functions, probabilistic clustering using mixture models is also popular. It is typically done by fitting multivariate Gaussian mixtures. While several approaches have been proposed for robust estimation and clustering under the existence of outliers (e.g. Coretto & Hennig, 2016; Fujisawa & Eguchi, 2006; Punzo & McNicholas, 2016; Sugawara & Kobayashi, 2022; Yang et al., 2012), such approach suffers from a huge number of parameters (especially for modeling covariance matrix) to be estimated when the dimension is large. Therefore, these approaches would not be a reasonable solution when our primary focus is on clustering.

To address the difficulty of a series of sparse trimming-cluster and probabilistic-cluster approaches, we propose a new approach based on regularization techniques for sparsity as well as robustness, called adaptively robust and sparse K -means (ARSK). We introduce an error component for each observation as an additional parameter to absorb the undesirable effects caused by outliers, making the clustering algorithm robust. We

employ a group lasso penalty and a group SCAD penalty to estimate these parameters during the clustering steps. Meanwhile, to reduce the data's dimension, we also introduce a lasso-type penalty or SCAD penalty to the weights for each variable to introduce sparsity and eliminate noise variables irrelevant to clustering. We then develop an efficient computation algorithm to minimize the proposed objective function. While the proposed method has two tuning parameters controlling robustness (the number of outliers to be detected) and sparsity (the level of the sparsity of the variable weight), we adopt a modified version of the Gap statistic (Tibshirani et al., 2001) to determine the optimal values of them. Hence, the level of robustness and sparsity is adaptively determined in a fully data-dependent manner.

The paper is organized as follows. Section 2 reviews the K -means algorithm and its extended model introduces the proposed method ARSK and presents its details and pseudocode. Additionally, in this section, we also outline the approach for selecting tuning parameters, accompanied by its corresponding pseudocode. Section 3 presents the tuning parameter selection results and demonstrates the application of both algorithms to various scenarios, including artificial datasets and several real-world datasets. This paper ends in Section 4 with concluding remarks. R code implementing the proposed method is available at GitHub repository (<https://anonymous.4open.science/r/ARSK-27D7>).

2 Robust and Sparse K -means Clustering

2.1 Conventional K -means algorithm

Suppose that we observe a p -dimensional vector, $x_{i,:} = (x_{i1}, \dots, x_{ip})$, for $i = 1, \dots, n$, and that we are interested in clustering $x_{i,:}$. Given the number of clusters, K , the conventional K -means algorithm aims to find the optimal clustering by minimizing the following objective function:

$$\min_{c_1, \dots, c_K} \sum_{k=1}^K \frac{1}{n_k} \sum_{i, i' \in c_k} (x_{i,:} - x_{i',:})^2, \quad (1)$$

where $(x_{i,:} - x_{i',:})^2$ is the L_2 -distance between two observed vectors. Here c_k is a set of indices representing a cluster of observations and n_k is the size of c_k , such that $\cup_{k=1}^K c_k = \{1, \dots, n\}$ and $\sum_{k=1}^K n_k = n$, where $c_k \cap c_{k'} = \emptyset$ for $k \neq k'$. The objective function (1) can be easily optimized by iteratively updating cluster means and assignment (e.g. Lloyd, 1982).

As demonstrated in Witten & Tibshirani (2010), the objective function (1) can be reformulated in terms of the between-cluster sum of squares, given by $\max_{c_1, \dots, c_K} \sum_{j=1}^p Q_j(x_{:,j}; \Theta)$, where

$$Q_j(x_{:,j}; \Theta) = \frac{1}{n} \sum_{i=1}^n \sum_{i'=1}^n (x_{ij} - x_{i'j})^2 - \sum_{k=1}^K \frac{1}{n_k} \sum_{i, i' \in c_k} (x_{ij} - x_{i'j})^2, \quad (2)$$

with $x_{:,j} = (x_{1j}, \dots, x_{nj})$ and Θ being a collection of c_1, \dots, c_K . Witten & Tibshirani (2010) employed the modified version of the objective function (2), given by $\sum_{j=1}^p \omega_j Q_j(x_{:,j}; \Theta)$ with an appropriate constrained on ω_j , for conducting variable selection and clustering simultaneously.

2.2 Robust and sparse K -means algorithm

The objective function (2) is sensitive to outliers since the approach relies on the L_2 distance between each observation. As a result, even a small quantity of deviating observations can affect the K -means algorithm. In order to enhance the robustness of the K -means approach, we modify the function $Q_j(x_{:,j}; \Theta)$ as follows:

$$\begin{aligned} Q_j^R(x_{:,j}; \Theta, E) &= \frac{1}{n} \sum_{i=1}^n \sum_{i'=1}^n \{(x_{ij} - E_{ij}) - (x_{i'j} - E_{i'j})\}^2 \\ &\quad - \sum_{k=1}^K \frac{1}{n_k} \sum_{i, i' \in c_k} \{(x_{ij} - E_{ij}) - (x_{i'j} - E_{i'j})\}^2, \end{aligned} \quad (3)$$

where E is an $n \times p$ error matrix, which is a collection of E_{ij} and E_{ij} is an additional location parameter for each x_{ij} such that E_{ij} will be non-zero values for outlying observations x_{ij} to prevent an undesirable effects from outliers. While the number of elements of E is the same as the number of observations, it can be assumed that E is sparse in the sense that most elements of E are 0. That is, most elements are not outliers. To stably estimate E , we consider penalized estimation for E_{ij} when optimizing the function (3). Such approaches are used in the robust fitting of regression models (e.g. She & Owen, 2011; Katayama & Fujisawa, 2017).

Based on the robust objective function (3), we propose an objective function for robust and sparse K -means algorithm as follows:

$$L(\Theta, E, W; \lambda) = \sum_{j=1}^p w_j Q_j^R(x_{:,j}; \Theta, E_{:,j}) - \sum_{i=1}^n P_1(\|E_{i,:}\|_2; \lambda_1) - \sum_{j=1}^p (P_2(w_j; \lambda_2) + \frac{1}{2} w_j^2), \quad (4)$$

where P_1 and P_2 are group penalty functions and penalty functions for sparse and shrinkage estimation of $E_{i,:}$ and w_j , respectively, and $\lambda = (\lambda_1, \lambda_2)$ is a set of tuning parameters. To ensure a unique solution for the weight coefficients w_j , we add a quadratic term $\frac{1}{2} \sum_{j=1}^p w_j^2$ to the objective function. Then, the robust and sparse K -means clustering can be defined as $\hat{\Theta}$ such that

$$(\hat{\Theta}, \hat{E}, \hat{W}) = \operatorname{argmax}_{\Theta, E, W \in \mathcal{H}} L(\Theta, E, W; \lambda).$$

$$\mathcal{H} = \left\{ w_j \in \mathbb{R}^+ : \sqrt{\sum_{j=1}^p w_j^2} = 1 \right\}$$

In what follows, we employ two specific forms of group penalty functions $P_1(\|E_{i,:}\|_2; \lambda_1)$: one type is the convex group penalty function, which is the group lasso penalty as $\lambda_1 \|E_{i,:}\|_2$ (Yuan & Lin, 2006), and the other type is the nonconvex group penalty function, which is the group SCAD penalty (Huang et al., 2012) as

$$P_{\lambda_1}^{SCAD}(\|E_{i,:}\|_2) = \begin{cases} \lambda_1 \|E_{i,:}\|_2 & \text{if } \|E_{i,:}\|_2 \leq \lambda_1 \\ -\left(\frac{\|E_{i,:}\|_2^2 - 2a\lambda_1 \|E_{i,:}\|_2 + \lambda_1^2}{2(a-1)}\right) & \text{if } \lambda_1 < \|E_{i,:}\|_2 \leq a\lambda_1 \\ \frac{(a+1)\lambda_1^2}{2} & \text{if } \|E_{i,:}\|_2 > a\lambda_1. \end{cases}$$

We also consider both convex and nonconvex penalties for the penalty term $P_2(w_j; \lambda_2)$: the convex standard lasso penalty $P_2(w_j; \lambda_2) = \lambda_2 |w_j|$ and, the non-convex SCAD penalty expressed as $P_2(w_j; \lambda_2) = P_{\lambda_2}^{SCAD}(w_j)$, where $P_{\lambda_2}^{SCAD}(w_j)$ define as:

$$P_{\lambda_2}^{SCAD}(w_j) = \begin{cases} \lambda_2 |w_j| & \text{if } |w_j| \leq \lambda_2 \\ -\left(\frac{|w_j|^2 - 2a\lambda_2 |w_j| + \lambda_2^2}{2(a-1)}\right) & \text{if } \lambda_2 < |w_j| \leq a\lambda_2 \\ \frac{(a+1)\lambda_2^2}{2} & \text{if } |w_j| > a\lambda_2. \end{cases}$$

When applying the L_1 or SCAD penalties, we seek the optimal weight vector of $W = (w_1, \dots, w_p)$, which is normalized to have a unit L_2 -norm, i.e., $\sqrt{\sum_{j=1}^p w_j^2} = 1$. This approach promote a more balanced solution (Zou & Hastie, 2010).

2.3 Optimization algorithm

The proposed objective function (4) can be optimized by iteratively updating each parameter. Regarding the updating of the clustering assignment Θ , we note that the maximization of $L(\Theta, E, W; \lambda)$ with respect to Θ under given E and W is equivalent to minimizing

$$L(\Theta|E, W; \lambda) = \sum_{j=1}^p w_j \sum_{k=1}^K \frac{1}{n_k} \sum_{i, i' \in c_k} \left\{ (x_{ij} - E_{ij}) - (x_{i'j} - E_{i'j}) \right\}^2.$$

The optimal solution to this equation is obtained by assigning each adjusted observation point to the sample mean of the adjusted observation with the smallest squared Euclidean distance (e.g. Lloyd, 1982), given by

$$\operatorname{argmin}_{\Theta} \sum_{j=1}^p \sum_{k=1}^K \sum_{i \in c_k} w_j \left\{ x_{ij} - E_{ij} - \frac{1}{n_k} \sum_{i \in c_k} (x_{ij} - E_{ij}) \right\}^2, \quad (5)$$

which can be easily computed by using the standard K -means algorithm.

Given clustering assignment Θ and variable weight W , the error matrix E can be updated as

$$\operatorname{argmin}_E \left\{ \frac{1}{2} \sum_{j=1}^p w_j \sum_{k=1}^K \sum_{i \in c_k} (x_{ij} - E_{ij}^* - \mu_{kj}^*)^2 + \sum_{i=1}^n P_1(\|E_{i,:}\|_2; \lambda_1) \right\}, \quad (6)$$

where $\mu_{kj}^* = n_k^{-1} \sum_{i \in c_k} (x_{ij} - E_{ij}^*)$ and E_{ij}^* is the optimized value of E_{ij} from the previous iteration.

As previously discussed, the variable E plays a crucial role in robustness. If an observation does not fall into any cluster, the presence of $E_{i,:}$ will lead to the assumption that this observation pertains to a particular cluster. The penalty $P_1(\|E_{i,:}\|_2; \lambda_1)$ controls the robustness of the model. We also note that under $\lambda_1 \rightarrow \infty$, all $E_{i,:}$ equal a p -dimensional zero vector. As a result, the objective function (6) becomes equivalent to traditional K -means clustering.

In the minimization problem (6), as previously mentioned, we employ the group lasso penalty and group SCAD penalty (Tibshirani, 1996; Antoniadis & Fan, 2001). The optimizers are obtained by applying the thresholding function corresponding to the group penalty to $x_{i,:} - \mu_{k,:}$. These two types of group penalty functions correspond to two distinct categories of thresholding functions: the group lasso penalty function corresponds to the multivariate soft-threshold operator, where $E_{i,:}$ can be calculated through

$$E_{i,:} = (x_{i,:} - \mu_{k,:}) \max \left(0, 1 - \frac{\lambda_1}{\|x_{i,:} - \mu_{k,:}\|_2} \right), \quad (7)$$

as proposed by Huang et al. (2012), while the group SCAD penalty function corresponds to the multivariate SCAD-threshold operator introduced by Huang et al. (2012), which $E_{i,:}$ is computed as:

$$E_{i,:} = \begin{cases} \mathbf{S}(\mathbf{z}; \lambda_1), & \text{if } \|\mathbf{z}\|_2 \leq 2\lambda_1 \\ \frac{a-1}{a-2} \mathbf{S}(\mathbf{z}; \frac{a\lambda_1}{a-1}), & \text{if } 2\lambda_1 < \|\mathbf{z}\|_2 \leq a\lambda_1 \\ \mathbf{z}, & \text{if } \|\mathbf{z}\|_2 > a\lambda_1. \end{cases} \quad (8)$$

where $\mathbf{z} = x_{i,:} - \mu_{k,:}$ and $\mathbf{S}(\mathbf{z}; \lambda)$ represents multivariate soft-threshold operator. In this paper, we set $a = 3.7$ as recommended in Fan & Li (2001).

In addition to the previously mentioned multivariate soft-threshold operator and multivariate SCAD-threshold operator, The application of the aforementioned methods can also be extended to the group MCP penalty associated with the multivariate MCP-threshold operator. However, due to its similarity to the SCAD penalty, we exclusively employed the SCAD penalty. Moreover, we suggest avoiding the application of the group hard penalty as optimizing it is inherently difficult. Furthermore, during our simulation process, we discovered that it is easy to converge to local minima.

As discussed by Witten (2013) and She & Owen (2011), this formulation establishes a connection between the framework of robust M-estimation and the proposed model (6) with clustering center μ_{kj}^* for each k held fixed.

As described above, the matrix of errors obtained from the algorithm is weighted based on the current weights. Therefore, it is necessary to restore the weighted error matrix E to its original unweighted state by dividing the current weight before we go to the next step to calculate the new weight for each variable (if the weight of a certain variable is zero, then $E_{:,j}$ will divide one instead of zero).

Finally, given E and Θ , the minimization of $L(\Theta, E, W; \lambda)$ with respect to W is equivalent to

$$\operatorname{argmax}_{W \in \mathcal{H}} \left\{ \sum_{j=1}^p w_j Q_j^R(x_{:,j}; \Theta, E_{:,j}) - \sum_{j=1}^p (P_2(w_j; \lambda_2) + \frac{1}{2} w_j^2) \right\}, \quad (9)$$

where $\mathcal{H} = \{w_j \in \mathbb{R}^+ : \sqrt{\sum_{j=1}^p w_j^2} = 1\}$. We demonstrate in the Appendix that the final solution to (9) can be donated as:

$$w_j = \frac{S(Q_j^R(x_{:,j}; \Theta, E_{:,j}); \lambda_2)}{\sqrt{\sum_{j=1}^p (S(Q_j^R(x_{:,j}; \Theta, E_{:,j}); \lambda_2))^2}},$$

When applying the $P_2(w_j; \lambda_2) = \lambda_2 |w_j|$ penalty in (9), the superscript S denotes the soft-thresholding operator as:

$$S(x; \lambda_2) = \begin{cases} x - \lambda_2, & \text{if } x > \lambda_2 \\ 0, & \text{if } |x| \leq \lambda_2 \\ x + \lambda_2, & \text{if } x < -\lambda_2. \end{cases}$$

When applying the $P_2(w_j; \lambda_2) = P_{\lambda_2}^{SCAD}(w_j)$ penalty in (9), the superscript S denotes SCAD-thresholding operator as:

$$S(x; \lambda_2) = \begin{cases} \operatorname{sgn}(x)(|x| - \lambda_2)_+ & \text{if } |x| \leq 2\lambda_2 \\ \{(a-1)x - a\lambda_2 \cdot \operatorname{sign}(x)\} / (a-2) & \text{if } 2\lambda_2 \leq |x| < a\lambda_2 \\ x & \text{if } a\lambda_2 \leq |x|. \end{cases}$$

The parameter λ_2 has a crucial role in regulating the sparsity of the variable weight vector. A higher value of λ_2 results in increased sparsity of the variable vector $W = (w_1, \dots, w_p)$. Specifically, a higher weight value w_j indicates greater importance of the j th variable in the clustering process. Conversely, when w_j is equal to zero, it signifies that the j th variable does not contribute to the clustering.

In order to gain a deeper comprehension of the algorithmic process we have proposed, we summarize the aforementioned procedures in a pseudocode in Algorithm 1.

2.4 Adaptation of the tuning parameters by the robust Gap statistic

There are two tuning parameters in the proposed algorithm: λ_1 and λ_2 . The tuning parameter λ_1 is crucial for finding the error matrix and impacts outliers' detection, and the tuning parameter λ_2 plays an essential role in filtering out variables contributing to the clustering process. We here provide the robust Gap statistic to determine these parameters.

The Gap statistic was originally proposed in Tibshirani et al. (2001) for selecting the number of clusters in the K -means algorithm. Note that the Gap statistic is constructed as a function of the between-cluster sum of squares, i.e., $D = \sum_{j=1}^p w_j (n^{-1} \sum_{i=1}^n \sum_{i'=1}^n (x_{ij} - x_{i'j})^2 - \sum_{k=1}^K n_k^{-1} \sum_{i, i' \in c_k} (x_{ij} - x_{i'j})^2)$, for the original dataset. However, since D is sensitive to outliers, it is not suitable for selecting the tuning parameters under existence of outliers. Hence, we propose a robust version of Gap statistic by adding the error part to each observation when calculating the $D_{\lambda_2, \lambda_1}^R$. As we mentioned before, the error part can outweigh the influence of the outlier, so that we define $\operatorname{Gap}_{\lambda_2, \lambda_1}$ as

$$\operatorname{Gap}_{\lambda_2, \lambda_1} = \log(D_{\lambda_2, \lambda_1}^R) - \frac{1}{B} \sum_{b=1}^B \log({}^{(b)}D_{\lambda_2, \lambda_1}^R), \quad D_{\lambda_2, \lambda_1}^R = \sum_{j=1}^p w_j Q_j^R(x_{:,j}; \Theta, E_{:,j}), \quad (10)$$

and the optimal value of λ_2 and λ_1 corresponding to the largest value of $\operatorname{Gap}_{\lambda_2, \lambda_1}$. Note that $D_{\lambda_2, \lambda_1}^R$ is a weighted robust between-cluster sum of squares defined in (3), and ${}^{(b)}D_{\lambda_2, \lambda_1}^R$ is a version for permuted

Algorithm 1 : Iterative algorithm for ARSK

- 1: Initialize the weight vector W as $w_j = 1/\sqrt{p}$, set tolerance $\varepsilon > 0$ and $r = 0$.
- 2: Initialize the error matrix by setting $E_{ij}^{(0)}$ of the 80% of data farthest from all data center points to x_{ij} ; the others set as 0.
- 3: **repeat**
- 4: Run the clustering algorithm on the weighted dataset $x_{ij}^* = w_j^{(r)}(x_{ij} - E_{ij}^{(r)})$ by

$$\max_{c_1, \dots, c_k} \left\{ \sum_{j=1}^p \left(\left(x_{ij}^* - \frac{1}{n} \sum_{i=1}^n x_{ij}^* \right)^2 - \sum_{k=1}^K \sum_{i \in c_k} \left(x_{ij}^* - \frac{1}{|n_k|} \sum_{i \in c_k} x_{ij}^* \right)^2 \right) \right\}.$$

- 5: Calculate the new E_{ij} by (7) or (8), which incorporates the cluster-specific means $\mu_{k,:} = |n_k|^{-1} \sum_j \sum_{i \in c_k} x_{ij}^*$.
- 6: Until the (6) converges, we can obtain the error matrix $E_{ij}^{(r+1)}$ and the cluster arrangement $\Theta^{(r+1)}$. Keep those results for the next variable selection phase.
- 7: Restore the error matrix by setting:

$$E_{ij}^{(r+1)} := E_{ij}^{(r+1)} / \sqrt{w_j^{(r)}}.$$

- 8: Arrange the cluster $\Theta^{(r+1)}$ and compute the $Q_j^R(x_{:,j}; \Theta^{(r+1)}, E)$ for different variables by:

$$Q_j^R(x_{:,j}; \Theta^{(r+1)}, E) = \sum_{i=1}^n \left(x'_{ij} - \frac{1}{n} \sum_{i=1}^n x'_{ij} \right)^2 - \sum_{k=1}^K \sum_{i \in c_k^{(r+1)}} \left(x'_{ij} - \frac{1}{|n_k|} \sum_{i \in c_k^{(r+1)}} x'_{ij} \right)^2,$$

where $x'_{ij} = x_{ij} - E_{ij}^{(r+1)}$.

- 9: Compute new variable weight by:

$$w_j^{(r+1)} = \frac{S(Q_j^R(x_{:,j}; \Theta, E_{:,j}); \lambda_2)}{\sqrt{\sum_{j=1}^p (S(Q_j^R(x_{:,j}; \Theta, E_{:,j}); \lambda_2))^2}}.$$

- 10: $r = r + 1$.
- 11: **until** convergence of the criterion $(\sum_j |w_j^{(r)}|)^{-1} \sum_j |w_j^{(r+1)} - w_j^{(r)}| < \varepsilon$ is met.
- 12: **Output**: w_j , E , Θ .

datasets. Here B denotes the number of permuted datasets, which are generated by randomly selecting from the original dataset. Increasing the number of permuted datasets leads to enhanced accuracy in selecting the true parameters. The between-cluster sum of squares, taking account of the variable weight, is adopted in Witten & Tibshirani (2010), so our version used in (10) can be regarded as its robust extension.

Since it may be computationally intensive to search the optimal value of (λ_2, λ_1) by a grid search method, we conduct an alternating optimization algorithm for tuning parameter search. Specifically, we first set a suitable value λ_1^\dagger for λ_1 and compute the optimal value λ_2^* of λ_2 by maximizing $\text{Gap}_{\lambda_2, \lambda_1^\dagger}$. Then, we obtain the optimal value λ_1^* of λ_1 by maximizing $\text{Gap}_{\lambda_2^*, \lambda_1}$. Using this search algorithm instead of the grid search method can save a significant huge of computation time. We also offer a pseudocode for this procedure for easy understanding of this search algorithm given in Algorithm 2.

Algorithm 2 : Selection of (λ_2, λ_1) by the robust Gap statistic

- 1: Set some value for λ_1^\dagger and maximize the following Gap statistic with respect to λ_2 :

$$\text{Gap}_{\lambda_2} = \log(D_{\lambda_2, \lambda_1^\dagger}^R) - \frac{1}{B} \sum_{b=1}^B \log({}^{(b)}D_{\lambda_2, \lambda_1^\dagger}^R)$$

to obtain the optimal λ_2^* .

- 2: Fix $\lambda_2 = \lambda_2^*$ and optimize the following Gap statistic with respect to λ_1 :

$$\text{Gap}_{\lambda_1} = \log(D_{\lambda_2^*, \lambda_1}^R) - \frac{1}{B} \sum_{b=1}^B \log({}^{(b)}D_{\lambda_2^*, \lambda_1}^R)$$

to obtain the optimal λ_1^* .

- 3: **Output**: the optimal set of tuning parameters, $(\lambda_2^*, \lambda_1^*)$.

3 Numerical Studies

3.1 Experimental setup

In this section, we explore the ability of the proposed clustering method. We consider that each observation x_i is generated independently from a multivariate normal distribution, given that the observation belongs to cluster k . Specifically, for an observation x_i in cluster k , we have $x_i \sim \mathcal{N}(\mu_{k,:}, \Sigma_p)$, where $\mu_{k,:} \in \mathbb{R}^p$ denotes the mean vector for cluster k , and $\Sigma_p \in \mathbb{R}^{p \times p}$ represents the covariance matrix. Each element of $\mu_{k,:}$ is independently sampled from either $U(-6, -3)$ or $U(3, 6)$. To simulate scenarios involving outliers, we introduce a contaminated error distribution with a multivariate normal mixture, represented as $(1 - \pi)\mathcal{N}(\mu_{k,:}, \Sigma_p) + \pi\mathcal{N}(\mu_{k,:} + b_j, \Sigma_p)$, $j = 1, \dots, p$ where $\pi \in [0, 1]$ represents the proportion of outliers for each cluster. In the simulation study, We consider two types of Σ_p . In the first scenario, the assumption is made that all variables are independent. In another scenario, we assume there is a correlation structure among variables. To introduce randomness to the appearance of outliers, b_j is generated with a random number from one of two uniform distributions: $U(-13, -7)$ or $U(7, 13)$. In this setup, we assume that some explanatory variables are significantly associated with the response, while the remaining variables are redundant for variable selection. To mimic this situation, we randomly set q elements of $\mu_{k,:}$ to non-zero values while the remaining elements are set to zero. Consequently, a successful method should accurately identify the q positions where the weights w_j corresponding to the true significant variables are non-zero while ensuring that the weights w_j of the remaining variables are set to zero.

To evaluate the approach's clustering accuracy capability, we employ the clustering error rate (CER) (Rand, 1971). The CER measures the extent to which the model's predicted partition \hat{C} for a set of n observations is consistent with the true labels C .

The CER is defined as

$$\text{CER}(\hat{C}, C) = \binom{n}{2}^{-1} \sum_{i < i'} |\mathbf{1}_{\hat{C}_{(i, i')}} - \mathbf{1}_{C_{(i, i')}}|, \quad (11)$$

where, $\mathbf{1}_{C_{(i, i')}}$ and $\mathbf{1}_{\hat{C}_{(i, i')}}$ indicate whether the i th and i' th observations belong to the same cluster. Lower CER indicates better performance in clustering accuracy or outlier detection.

Furthermore, in order to evaluate each method's proficiency in variable sparsity, we apply two criteria for variable selection. The variable true positive rate (TPR) indicates the approach's success in finding informative variables. The true negative rate (TNR) represents the successful identification of non-informative variables. If both criteria are closer to 1, it indicates that the model provides a more comprehensive explanation of the structure of the variables predicted in the study.

3.2 Simulation 1: selection of turning parameter

In this subsection explores the new Gap statistic' capability to directly search for the tuning parameters of robustness and variable vector sparsity using Algorithm 2. Initially, we considered 3 clusters, each containing 50 observations, number of variables as $p = 50$, with $q = 5$, and all variables are independent, i.e., $\Sigma_p = I_p$. A proper of hyperparameters λ_1 and λ_2 should enable the model to accurately identify the number of outliers and the number of informative variables in different contamination levels for π in $\{0, 0.1, 0.2, 0.3\}$. The proposed tuning parameter search strategy generates both the robustness parameter λ_1 and the variable selection tuning parameter λ_2 using an exponential decay. We consider the number of permuted datasets to be 25 (i.e., $B = 25$). We employed different thresholding function types, where the first thresholding function is used to control model sparsity, and the second thresholding function is used to control model robustness. The tuning parameter search process is repeated 30 times for 30 different datasets, and the resulting table is presented in Table 1.

Table 1: Using the robust Gap statistic to select the optimal tuning parameters for the RSKC algorithm based on soft-soft-thresholding, soft-SCAD-thresholding, SCAD-soft-thresholding, and SCAD-SCAD-thresholding, we report the average and its standard error (in parentheses) of the number of detected outliers and the number of detected informative variables.

threshold type	contamination level	number of detected outliers	number of detected informative variable
soft-soft	$\pi = 0$	0(0)	4.300(0.000)
	$\pi = 0.1$	15.56(6.425)	4.533(0.618)
	$\pi = 0.2$	28.73(2.434)	4.200(0.871)
	$\pi = 0.3$	33.10(14.76)	13.60(7.203)
soft-SCAD	$\pi = 0$	0(0)	4.400(0.000)
	$\pi = 0.1$	14.43(0.495)	6.310(1.854)
	$\pi = 0.2$	28.68(1.349)	4.566(0.495)
	$\pi = 0.3$	42.36(2.287)	6.800(2.946)
SCAD-soft	$\pi = 0$	0(0)	4.545(0.687)
	$\pi = 0.1$	14.30(0.483)	5.400(0.469)
	$\pi = 0.2$	27.11(6.166)	5.941(1.748)
	$\pi = 0.3$	38.63(16.63)	9.272(4.540)
SCAD-SCAD	$\pi = 0$	0.090(0.333)	4.272(0.881)
	$\pi = 0.1$	13.33(1.258)	5.833(3.125)
	$\pi = 0.2$	24.10(5.065)	4.500(2.068)
	$\pi = 0.3$	44.00(4.2110)	7.187(1.223)

Table 1 summarizes the results of the evaluation measures. Overall, an effective tuning parameter λ_1 should accurately identify the number of outliers under different contamination levels. As the contamination level π increases from 0 to 0.3, we observe that the four thresholding methods demonstrate diverse outlier detection capabilities across different contamination levels. At $\pi = 0.1$, the detected number of outliers ranges from 13.33 to 15.56, with soft-soft-thresholding achieving the highest average of 15.56 (standard error: 6.425). When π increases to 0.2, the detected number of outliers falls between 24.10 and 28.73, with soft-soft and soft-SCAD-thresholding showing similar performance. This demonstrates that the Gap statistic can help the ARKC method determine λ_1 to some extent. However, when the contamination level reaches 0.3, the soft-soft-thresholding ARSK method detects 33.10 outliers on average, which is lower than the SCAD-SCAD-thresholding ARSK method (44.00 outliers), and deviates from the true number of outliers.

Regarding the selection of the tuning parameter λ_2 , a effective tuning parameter should accurately identify the number of informative variables under different contamination levels. When the data is clean ($\pi = 0$), all four methods identify around 4 to 5 informative variables, which is close to 5. As the contamination level increases, the number of detected informative variables generally increases, with some fluctuations. At $\pi = 0.3$, the soft-soft-thresholding ARSK method detects 13.60 informative variables on average, which significantly deviates from the 5. In contrast, the SCAD-SCAD-thresholding ARSK method detects 7.187

informative variables, showing better performance in the presence of high contamination. Furthermore, errors in identifying informative variables can lead to significant biases in outlier detection.

Considering these results, we can conclude that the proposed parameter selection algorithm based on the Gap statistic works relatively well under low to moderate contamination levels. However, its performance may degrade when the contamination level is high, especially for the soft-thresholding-based methods. The SCAD-thresholding-based methods generally show better robustness and accuracy in identifying outliers and informative variables under high contamination levels.

3.3 Simulation 2: comparison with other methods

In this subsection, we present the findings of a comprehensive simulation study conducted to investigate the cluster data structure and properties by the ARSK algorithm based on soft-thresholding and SCAD-thresholding. The study extensively applied the Gap statistic to estimate optimal parameter settings and compared the results with several benchmark approaches, including K -means (KC), PCA- K -means (PCA-KC) clustering using only the first principal component, trimmed K -means (TKM), robust and sparse K -means RSKC ($\alpha = 0.1, 0.2$) (Kondo et al., 2016), and the weighted robust K -means (WRCK) algorithms (Brodinova et al., 2019). Note that WRCK and RSKC are both trimming-based clustering approaches.

Considering the mixture error model mentioned at the beginning, we also generated data for 3 clusters, each containing 50 observations. We set the number of variables as $p = 50$, with $q = 5$, and $p = 500$, with $q = 50$. Meanwhile, we consider π in $\{0, 0.1, 0.2\}$ for specifying the distribution of outliers. As previously stated, we study two types of covariance matrices: one with $\Sigma_p = I_p$ and the another type of Σ_p generated according to the method proposed by Hirose et al. (2017) as

$$\Sigma_p = Q \begin{bmatrix} 1 & \rho_t & \cdots & \rho_t \\ \rho_t & 1 & \ddots & \rho_t \\ \vdots & \ddots & 1 & \vdots \\ \rho_t & \cdots & \rho_t & 1 \end{bmatrix} Q^T,$$

where the Q denotes a $p \times p$ random rotation matrix satisfying $Q^T = Q^{-1}$ and the ρ_t are randomly generated from an Uniform distribution $U(0.1, 1)$.

In order to evaluate the clustering accuracy and outlier detection capability of each approach, we employ the clustering error rate (CER) as described above. To assess the outlier detection performance, the outliers identified by each model are assigned to the $(K + 1)$ -th cluster group. Table 2 presents the results of 100 simulations for the scenario where all variables are independent, i.e., $\Sigma_p = I_p$, while Table 3 summarizes the results of 100 simulations for the scenario where variables demonstrate a certain correlation structure.

Table 2: When variables are independent, the average values of the CER and their standard errors (in parentheses) based on 100 Monte Carlo replications.

In Tables 2 and 3, the results show that KC, PCA-KC, and TKM approaches, which lack robustness for high dimensions or outliers, are the poorest performers, particularly when the dimensionality p and proportion of outliers π increase. For instance, in the independent case with $p = 500$ and $q = 50$, the CER of KC increases from 0.050 to 0.341 as π increases from 0 to 0.2. Similarly, the CER of PCA-KC and TKM ($\alpha = 0.1$) increase from 0.058 to 0.300 and 0.128 to 0.302, respectively, under the same scenario. Conversely, RSCK, WRCK, and ARSK perform exceptionally well in high-dimension and high-contamination scenarios. However, the effectiveness of the RSCK approach heavily depends on the choice of the parameter α . When α equals the true outlier proportion, RSCK performs impressively, with CER close to 0. For example, in the correlated case with $p = 500$ and $q = 50$, the CER of RSKC ($\alpha = 0.1$) is 0 when $\pi = 0.1$. However, the approach loses effectiveness if α is incorrectly specified, leading to higher CER values. In the same scenario, the CER of RSKC ($\alpha = 0.2$) is 0.122 when $\pi = 0.1$. The WRCK approach, based on the density clustering method, generally outperforms RSCK when outliers are present. Still, it may erroneously classify more normal data points as outliers when no contamination exists. In contrast, the ARSK approach, with different combinations of thresholding functions (e.g., soft-soft, soft-SCAD, SCAD-soft and SCAD-SCAD), consistently maintains a low CER across all simulated data scenarios.

In summary, the simulation results demonstrate the effectiveness and robustness of the Adaptive Robust Sparse K-means (ARSK) method in clustering high-dimensional datasets. Across diverse data scenarios, the ARSK variants consistently outperform traditional methods, including K-means (KC), PCA-K-means (PCA-KC), Trimmed K-means (TKM), Robust and Sparse K-means (RSKC), and Weighted Robust K-means (WRCK), highlighting the distinct advantages of the ARSK approach.

Both In Table 2 and Table 3, we observe that the CER of KC is worse than ARSK when there are no outliers in the dataset. Moreover, when $\pi = 0.1$, the CER of the TKM method is significantly higher than that of the RSCK method. We attribute this result to the presence of noisy variables, which contribute to the increased CER. Therefore, it is essential to identify these noisy variables to reduce their impact.

Through 100 repetitions, the results of the TPR and TNR are presented in Tables 4 and 5. As the proportion of outliers increases from 0 to 0.2, both the TPR and TNR of most approaches demonstrate a decreasing trend across different scenarios, suggesting that the presence of outliers can negatively influence the variable selection performance. However, the TPR and TNR of each type of ARSK approach variant remain relatively high and stable across various data scenarios, demonstrating ARSK’s superior variable selection capabilities in the presence of outlier contamination in datasets. For example, in the independent case with $p = 500$ and $q = 50$, the TPR of soft-soft-ARSK, soft-SCAD-ARSK, SCAD-soft-ARSK, and SCAD-SCAD-ARSK remain above 0.797, 0.818, 0.798, and 0.810, respectively, even when $\pi = 0.2$. Similarly, their TNR values stay above 0.977, 0.980, 0.978, and 0.981 in the same scenario. These results emphasize the superior ability of soft-ARSK and SCAD-ARSK methods to accurately identify informative and non-informative variables in the presence of outliers, making them valuable tools for handling contaminated clustering datasets.

In contrast, during the simulation process, we observed that traditional trimmed approaches such as WRCK and RSKC often struggled to maintain their variable selection performance under high outlier proportions. In many cases, these methods incorrectly assigned non-zero weights to variables that originally had zero weights, leading to an increased number of false negatives. This limitation makes it challenging for WRCK and RSKC to effectively detect informative variables in the presence of outliers, emphasizing the need for more effective methods like ARSK.

Table 4: When variables are independent, the average of 100 tests of TPR and TNP for variable selections and its standard error(in parentheses) are presented for the various data scenarios.

3.4 Applications to real data

In this subsection, we apply ARSK with different thresholding configurations to real-life datasets and compare it with the benchmark methods previously mentioned in the simulation study. We consider the dataset all from the UCI Machine Learning Repository (Dua & Graff (2019)). The assessed datasets include various applications, such as glass identification, breast cancer diagnosis, acoustic signal classification, spam base detection, mortality analysis, and Parkinson’s disease detection. The real-life dataset comprises data with a wide range of dimensions, ranging from low to high. As in the previous analysis, we also applied the Gap

Table 6: Comparison of CERs of different algorithms for the real-world data. The smallest and second smallest CER values are shown in bold.

statistic to estimate the hyperparameter. Due to the different units of the continuous variables, we normalize all of continuous variables before conducting the study.

Table 6 summarizes the result of the real-life dataset comparison. The reported values are CERs for each approach. In order to better illustrate the performance of that method, we have emphasized the first and second best CER values in bold when applied to a certain real-life dataset. While traditional methods such as KC, PCA-KC, and TKM demonstrate effectiveness in certain contexts, they generally yield higher CERs across the datasets compared to the proposed ARSK algorithm and its variants. For instance, in the glass and Breast Cancer dataset, the CER values obtained by KC, PCA-KC, and TKM are considerably higher than those of the best-performing ARSK. In seven real-world datasets, our ARSK method ranked among the top two best methods in six of the datasets. Therefore, the proposed ARSK algorithm consistently achieves superior performance with lower CERs across most of the real datasets, particularly when using the multivariate soft-threshold operator to obtain the error matrix E . ARSK demonstrates competitive performance in this regard.

This comparative analysis emphasizes the ARSK algorithm’s success in significantly reducing classification error rates across diverse real-world datasets, showcasing the versatility and adaptability of our proposed clustering method. Its different configurations (e.g., soft-soft, soft-SCAD, SCAD-soft and SCAD-SCAD), allow it to handle various data structures and sizes effectively. The consistent performance across different real-world datasets underscores the broad applicability of our approach in various fields.

4 Concluding remarks

In this paper, we propose an Adaptively Robust and Sparse K -means Clustering algorithm designed to handle multiple tasks within a unified framework for a comprehensive analysis of contaminated high-dimensional datasets. Our approach demonstrates greater flexibility in handling outliers within real-world datasets. We also proposed a modified Gap statistic with an alternating optimization algorithm to search for tuning parameters. This approach significantly reduces the computational time required for parameter tuning compared to traditional methods. The experimental results demonstrate the significant capabilities of the proposed approach in revealing group structures in high-dimensional data. Our model not only performs well in detecting outliers but also identifies significant variables directly, leading to a more thorough understanding of complex clustering datasets.

In our current study, we assume that the number of clusters is known, which is consistent with the traditional K -means method. Additionally, Chen & Witten (2023) proposed a test to detect differences in means between each cluster estimated from K -means clustering. This technique can be applied to the modified dataset $x_{ij} - E_{ij}$, where noise variables (i.e., $w_j = 0$) are removed, to help determine which clusters should be retained.

Furthermore, We have consistently utilized a single penalty factor λ_1 in the objective function (4). This implements a uniform approach to detecting outliers across various groups. However, given the complexity and diversity of the data, a more sophisticated strategy may be required. This might involve using different penalty factors, or distinct group penalty functions for different groups. One might employ $\sum_k \sum_{i \in c_k} P_k(E_{i,:}; \lambda_k)$

in (4). Incorporating this approach into unsupervised learning presents challenges in selecting not just the penalty factor but also the group penalty function. These extensions are left to our future work.

A Appendix

A.1 Proofs solution to (9)

Consider maximizing the following regularized objective function for estimating the weights w_j .

$$L(w_j, \lambda_2) = \sum_{j=1}^p W_j Q_j - \sum_{j=1}^p (P_2(w_j; \lambda_2) + \frac{1}{2} w_j^2),$$

where $Q_j = Q_j^R(x_{:,j}; \Theta, E_{:,j})$.

Taking the derivative with respect to w_j and setting it to zero, we obtain:

$$Q_j - w_j - \Gamma_j = 0.$$

When the L_1 penalty $P_2(w_j; \lambda_2)$ is applied, Γ_j represents the subgradient of the L_1 penalty with respect to w_j . Solving the above equation yields:

$$S^{\text{soft}}(x; \lambda_2) = w_j = \begin{cases} Q_j - \lambda_2, & \text{if } Q_j > \lambda_2 \\ 0, & \text{if } |Q_j| \leq \lambda_2 \\ Q_j + \lambda_2, & \text{if } Q_j < -\lambda_2. \end{cases}$$

When the SCAD penalty $P_2(w_j; \lambda_2)$ is applied, Γ_j represents the subgradient of the SCAD penalty with respect to w_j . Solving the above equation yields:

$$S^{\text{SCAD}}(x; \lambda_2) = w_j = \begin{cases} \text{sgn}(Q_j)(|Q_j| - \lambda_2)_+ & \text{if } |Q_j| \leq 2\lambda_2 \\ \frac{(a-1)Q_j - a\lambda_2 \cdot \text{sgn}(Q_j)}{(a-1)-1} & \text{if } 2\lambda_2 \leq |Q_j| < a\lambda_2 \\ Q_j & \text{if } a\lambda_2 \leq |Q_j|. \end{cases}$$

After project \hat{w}_j onto the parameter space $\sqrt{\sum_{j=1}^p w_j} = 1$, The final solution can be rewritten as:

$$w_j = \frac{S(Q_j; \lambda_2)}{\sqrt{\sum_{j=1}^p (S(Q_j; \lambda_2))^2}}.$$
