# Interpreting token compositionality in LLMs: A robustness analysis

#### Anonymous ACL submission

#### Abstract

Understanding the internal mechanisms of large language models (LLMs) is integral to enhancing their reliability, interpretability, and inference processes. We present Constituent-004 Aware Pooling (CAP), a methodology designed to analyse how LLMs process compositional 007 linguistic structures. Grounded in principles of compositionality, mechanistic interpretability, and information theory, CAP systematically intervenes in model activations through constituent-based pooling at various model levels. Our experiments on inverse definition mod-012 elling, hypernym and synonym prediction reveal critical insights into transformers' limita-015 tions in handling compositional abstractions. No specific layer integrates tokens into unified semantic representations based on their 017 constituent parts. We observe fragmented information processing, which intensifies with model size, suggesting that larger models struggle more with these interventions and exhibit greater information dispersion. This fragmentation likely stems from transformers' training objectives and architectural design, preventing systematic and cohesive representations. Our findings highlight fundamental limitations in current transformer architectures regarding 027 compositional semantics processing and model interpretability, underscoring the critical need for novel approaches in LLM design to address these challenges.

#### 1 Introduction

Large language models (LLMs) based on Transformer architectures have rapidly expanded in scope and capability, demonstrating strong performance across a wide range of NLP tasks. However, critical limitations remain, including hallucinations, poor interpretability, and limited semantic transparency. One open challenge concerns *linguistic compositionality*: how models combine smaller units of text (e.g., morphemes, words, phrases) into coherent meaning structures, and how this process is reflected in internal representations.

Understanding how and where compositional structure is encoded in LLMs is essential for bridging the gap between user intent and model behaviour. Prior work has explored this by aligning model inputs and outputs (Yin et al., 2024), embedding spaces (Haslett, 2024), or layer-wise activations (Yu and Ettinger, 2020; Modarressi et al., 2023) with expected semantic representations. These approaches are grounded in two intuitive assumptions: (1) that LLMs internally represent compositional structure at the token or word level, and (2) that this information should be at least partially localisable at specific layers during inference.

Several studies have revealed that LLMs are often brittle under perturbation (Wang et al., 2023; Fodor et al., 2024; Hu et al., 2024), and that phraselevel representations may fail to align with expected semantics (Carvalho et al., 2025). Despite this, the mechanisms behind such fragility, particularly at the level of internal activations, remain poorly understood.

To investigate this, we propose *Constituent-Aware Pooling (CAP)*, a structured perturbation method that groups token-level activations into larger constituent units (e.g., words or phrases) at arbitrary layers. CAP enables systematic probing of whether, and where, semantic meaning is robustly composed within the model. By applying CAP at varying depths, we assess the fragility of internal representations to compositional perturbations and examine whether, and how, semantic abstraction is distributed across layers.

Our empirical findings challenge common assumptions of hierarchical semantic buildup. Rather than gradually constructing compositional meaning across layers, LLMs often retain token-level focus well into the middle layers. Applying CAP, even at semantically coherent groupings, results

Figure 1: Illustration of the CAP process. Constituent segmentation identifies linguistic units (e.g., words or phrases), and CAP pools their activations at layer m using aggregation (e.g., max, mean, sum). This operation reduces sequence length, and the modified activations are propagated to layer m+1. The results graph shows task accuracy under CAP at different depths.

in substantial accuracy degradation, especially in earlier layers. Surprisingly, larger models are more sensitive to such perturbations than smaller ones, suggesting increased representational fragility with scale.

We contextualise these results using an information-theoretic lens, proposing that Transformer models delay aggregation to maximise token-level information throughput. This leads to distributed, rather than localised, composition across layers, resulting in longer dependency paths and reduced mutual redundancy at each layer.

In summary, our contributions are:

- A systematic analysis of how current LLMs handle constituent-level composition, evaluated via CAP across layers, models, and tasks.
- A theoretical explanation grounded in information theory, suggesting that LLMs optimise for prediction by postponing semantic integration, thus fragmenting compositional meaning across depth.

We conclude that compositional semantics are not reliably localisable within any fixed layer of standard Transformer models. This holds across model scales, supervision types, and inference tasks, and instead appears tied to architectural depth. Our results suggest that recovering explicit compositional structure may require specialised training objectives or architectural constraints. Supporting code and datasets are available at a public repository<sup>1</sup>.

# 2 Tokenisation and compositionality in LLMs

Intuitively, aggregating the representations of tokens that compose a single meaning unit (e.g., averaging the embeddings of 'm', 'amm' and 'al' to form a single token embedding) and then to larger phrasal units (e.g. adjectival and noun compositions), would have a relatively small impact on model inference, since they have a strong dependence on each other in a given context and thus share significant information. However, it has been shown that LLMs are highly sensitive to token placement (Yin et al., 2024; Hu et al., 2024) and that their internal representations have no significant correlation with phrasal composition semantics (Yu and Ettinger, 2020; Carvalho et al., 2025).

The observed disconnection between LLM internal representations and linguistic knowledge regarding compositionality raises practical and theoretical questions towards the robustness of such models to perturbations strictly tied to composi-

<sup>&</sup>lt;sup>1</sup>< anonymised url>

tional semantics (Appendix A). Such questions are 135 especially relevant in solving semantic gaps be-136 tween input prompts and expected responses, as 137 well as localising linguistic knowledge and improv-138 ing interpretability. One way in which they can be addressed is by systematically assessing the impact 140 of said perturbations on model inference perfor-141 mance, at each model layer. We elaborate on the 142 methodology to achieve this goal in the following 143 section. 144

### 3 Assessing compositional aggregation robustness

145

146

157

To accurately assess the effects of compositional 147 148 grouping at different layers of abstraction within transformer models, the inference objective should 149 be a task that is both: 1) strictly dependent on the 150 input tokens and their composition, with few pos-151 sible input variations; 2) contains as few tokens as 152 possible in the output. For this reason, the follow-153 ing tasks were selected (Figure 1): 154

- 1551. Inverse definition modelling (IDM): predicting a156term given its definition.
  - **2.** Synonym prediction (SP): producing a synonym for a given word.
- **3.** Hypernym prediction (HP): generating a more general term for a given word.
- Formal task definitions and input formats are detailed in Appendix B.1.
- Constituent-Aware Pooling (CAP). To introduce 163 compositional perturbations, we propose CAP, a 164 method for pooling (i.e., grouping) LLM activa-165 tions corresponding to individual tokens into cohe-166 sive linguistic units. CAP operates at two levels: 167 (i) word-level: grouping tokens that form a sin-168 gle word, and (ii) phrase-level: grouping tokens 169 that form a single phrase. At the word-level, CAP 170 reverse-maps each model's tokeniser to reconstruct 171 complete words and identify their activation ranges. 172 At the phrase-level, CAP uses a syntactic parser, 173 such as Benepar (Kitaev et al., 2019; Kitaev and 174 Klein, 2018), to align tokens with their correspond-175 ing phrasal constituents and define their activation 176 ranges. Further details on the parser evaluation 177 methodology are provided in Appendix D. 178
- 179**CAP Pooling Protocols.** CAP is applied progres-180sively across layers using three protocols  $\alpha$ : Max:181selects the maximum activation within a segment,182identifying dominant features and their propaga-183tion through layers; Mean: computes the average184activation, providing a balanced representation of

all token contributions and their collective impact on model decisions; and *Sum:* sums the activations, capturing cumulative information flow and aggregates effects of token interactions. These protocols offer complementary insights into how models process and integrate information: Max reveals feature prominence patterns, Mean shows distributed representation effects, and Sum reflects accumulated semantic content across segments.

Transformer conceptualisation and the formalisation of CAP. This work builds on the mathematical framework of transformers introduced by (Elhage et al., 2021), where computation is formalised into sequential residual blocks. Each layer reads inputs from the residual stream, processes them through its components (attention heads and feed-forward neural networks (FF)), and writes the outputs back into the residual stream. Attention heads are responsible for transferring information between tokens through the self-attention mechanism, allowing each token to attend to others in the sequence. FF apply non-linear transformations independently to each token representation, enhancing the model's expressive capacity. The residual stream stores and propagates information across layers, enabling the integration of new outputs with existing representations while preserving original input information through residual connections. Let the transformer model have L layers, input sequence of length K, batch size B, and inner activations X, with with tensor shapes varying by model component as follows:

- Attention layers output:  $X \in R^{B \times K \times H_m}$ , where  $H_m$  is the hidden dimension after projection.
- FF:  $X \in R^{B \times K \times H_f}$ , where  $H_f$  is the feed-forward dimension.
- Residual stream:  $X \in R^{B \times K \times H_h}$ , where  $H_h$  is the hidden dimension.

Let  $S = \{(s_1, e_1), \dots, (s_n, e_n)\}$  be the set of syntactic unit ranges (e.g., tokens, words or phrases), where  $s_i$  and  $e_i$  denote the start and end indices of the *i*-th range. CAP pools/groups activations within these ranges, reducing the sequence dimension Kto a grouped dimension G, where

$$G = K - \sum_{i=1}^{n} (e_i - s_i) \tag{1}$$

For each syntactic unit, CAP applies the grouping231function  $\alpha$  over the range  $[s_i, e_i]$  in one of three232

ways, formalised as follows:

Sum: 
$$\alpha([s_i, e_i]) = \sum_{t=s_i}^{e_i} X[t]$$
 (2)

(4)

**Mean:**  $\alpha([s_i, e_i]) = \frac{1}{e_i - s_i + 1} \sum_{t=1}^{e_i} X[t]$  (3)

**Max:**  $\alpha([s_i, e_i]) = \max_{t \in [s_i, e_i]} X[t]$ 

The grouped activations transform as follows:

• For attention layers output,  $X \in R^{B \times K \times H_m}$ 

• For FF,  $X \in R^{B \times K \times H_f}$  becomes  $X \in R^{B \times G \times H_f}$ .

• For residual stream:,  $X \in R^{B imes K imes H_h}$  be-

This process consolidates activations for each syn-

tactic unit, enabling systematic evaluation of com-

positional robustness across layers. For simplicity,

we demonstrate the operation over these compo-

becomes  $X \in R^{B \times G \times H_m}$ .

comes  $X \in R^{B \times G \times H_h}$ .

nents, but this approach can be extended to any

transformer's components, provided that the di-251 mensional requirements for information flow, as described in (Elhage et al., 2021), are respected. For example, consider attention layer internal activations of shape  $X \in \mathbb{R}^{B \times H_a \times K \times K}$ , where  $H_a$  is the number of attention heads, and K represents the 256 query and key token dimensions. Applying CAP 257 with the Sum protocol involves aggregating activations over the query range  $[s_i, e_i]$  and the key range  $[s_i, e_i]$ . The grouped activations are computed as:  $\alpha([s_i, e_i], [s_j, e_j]) = \sum_{t=s_i}^{e_i} \sum_{t'=s_j}^{e_j} X[b, h, t, t'].$ After applying CAP, the grouped activations have 261 the shape  $X \in \mathbb{R}^{B \times H_a \times G \times G}$ , where G is the number of grouped syntactic units. This ensures that query-key interactions are consolidated into co-265 hesive syntactic units, aligning activations with higher-level linguistic structures. We examine 267 CAP's reduction ratio  $(K \rightarrow G)$  at the word-level and its effects across models, with detailed anal-269 ysis in Appendix C. We refer the reader to Appendix B.4 for further details on how CAP affects 271 sequence length and interacts with positional en-273 codings. 274

The CAP effect on models is evaluated by measuring their accuracy post-CAP on a baseline test consisting of examples correctly predicted by the original models. This ensures that the evaluation

focuses on instances where CAP directly tests compositional robustness. Specifically, we report three key metrics: the original accuracy  $(A_{o})$ , which represents the model's accuracy on the baseline test before applying CAP and establishes a reference for evaluating the grouping effect; the grouped accuracy  $(A_c)$ , which measures the model's accuracy post-CAP, averaged across all CAP protocols (sum, mean, max) and reflects how well the model retains its predictions after compositional grouping; and the accuracy drop ( $\Delta A$ ), defined as  $\Delta A = A_o - A_c$ , which quantifies the performance loss due to CAP, where lower  $\Delta A$  values indicate more robust compositional behaviour and better preservation of semantic information across layers. These metrics offer a framework for comparing tasks and models, allowing a granular assessment of compositional representations.

and metrics. The CAP Datasets effect three WordNet-derived evaluated using is datasets—definitions, hypernyms, and synonyms-corresponding to the IDM, HP, and SP tasks (Fellbaum, 1998). Test examples correctly predicted by the original models  $(A_0)$  form the baseline for subsequent CAP evaluation. Grouped accuracy  $(A_c)$  is calculated post-CAP for this subset, ensuring that CAP's effect is isolated to examples where the original models performed correctly. The drop in accuracy ( $\Delta A$ ) is reported per protocol (sum, mean, max) to assess the impact of different aggregation methods on model performance. See Appendix B.2 for dataset details and Appendix E.3 for comprehensive results.

LLMs and evaluated dimensions. The methodology was tested across various decoder-only transformer models (Vaswani, 2017). Our main focus was on GPT-2 (small: 124M, medium: 355M, large: 774M parameters) (Radford et al., 2019), Gemma1 (2B parameters) (Team et al., 2024), Llama (3B, and 8B parameters) (Dubey et al., 2024), and Qwen (0.5B, 1.5B, and 3B parameters) (Yang et al., 2024). These models use different tokenisation approaches: byte-level BPE (GPT-2, Qwen), expanded BPE with 128K vocabulary (Llama3), and SentencePiece (Gemma). Models were tested before and after task-specific fine-tuning (3 epochs, learning rate 5e-5). This selection spans diverse architectures, sizes, and tokenisation strategies (see

Table 1: IDM accuracy drop  $\Delta$  in the word-level CAP, highlighting best and worst values in both original and fine-tuned models. The layer numbers were normalised to layer positions as percentages of the total layers, which allows comparing equivalent relative depths across models, such as 25% or 75% of the total layers, rather than using absolute layer numbers. This method ensures fair comparisons between models, even with different architectures.

Appendix B.3 for further details on the models and fine-tuning parameters).

**Experimental setup.** All experiments were conducted using 2x NVIDIA RTX A6000 and 2x NVIDIA RTX A100 GPUs, with the experimental framework being developed in Python 3.11.5. We used the Transformers (v4.44.2) and PyTorch (v2.4.1) libraries, along with Transformer-lens (v2.6.0), to train and evaluate models and for probing. Benepar (v0.2.0) was used for sentence parsing, and statistical analysis was supported by Scikitlearn (v1.5.2).

**Compositional inference in LLMs is not a purely incremental process.** Contrary to expectations of a smooth and steady layer-wise performance improvement, we observe significant fluctuations when CAP is applied across layers. Performance drops notably in early and middle layers, followed by sharp improvements (Figure 2 (a)-(c), (e), and (f)), suggesting these layers struggle to process CAPed activations, particularly the pooled linguistic features captured in earlier layers. *Rather than progressively building semantic information from individual tokens to complex phrases, the models appear to focus heavily on isolated token features.* 

An important distinction arises between **TW-CAP**, which groups tokens according to modelspecific tokenisation, and **TP-CAP**, which applies externally parsed syntactic structures. While TP-CAP introduces richer constituent information, it may not align with the model's internal segmentation or syntactic reasoning. This misalignment is not a flaw in CAP, but rather a diagnostic signal: if LLMs encoded human-like syntax, TP-based grouping should be minimally disruptive. The observed drop in performance under TP-CAP suggests that LLMs do not consistently internalise hierarchical syntactic structures. This finding underscores the model's emphasis on local token-level information and supports the conclusions drawn in our information-theoretic analysis.

The results indicate that attention is distributed over input tokens and model layers in a nonsystematic and decentralised manner that is highly context-dependent, showing minimal reliance on sequential or positional relationships of constituents. This phenomenon is particularly evident in the sharp decline in SP and HP tasks, where contextual information is limited during phrase-level CAP application. We argue that this behaviour stems from the model's training objective, which maximises information gain in each layer towards predicted tokens at the cost of reducing mutual information between tokens in a single layer. This behaviour means that aggregation, including syntactic, is performed across multiple layers and thus is not localisable from any single given layer. An information theoretical analysis elaborates this reasoning in Section 5. Our findings highlight how compositional structures are highly sensitive to token representation dynamics across layers, suggesting that performance fluctuations can be attributed

to information loss incurred as a function of token
mutual information across layers.

Larger models are more fragile to compositional perturbations. The IDM task highlights this fragility in larger models, as larger models rely on finer feature extraction. Within families, 396 distinct patterns emerge: original Owen's smaller 397 variants show better IDM robustness (e.g., at position 25% there was a 7.69% drop on Qwen-1.5B vs 12.11% on Qwen-3B), while Llama3 exhibits 400 capacity-dependent behaviour with the 3B variant 401 being more vulnerable than 8B. Despite having 402 similar reduction ratios to Llama models (see Ap-403 pendix C), Gemma-2B shows greater sensitivity to 404 perturbations (e.g., at position 1% Max: Gemma-405 2B drops 97.91% vs. Llama3-8B's 25.49%), likely 406 due to its larger vocabulary enabling finer-grained 407 tokenisation. While fine-grained token knowledge 408 benefits standard tasks, it appears to increase sus-409 ceptibility to compositional perturbations. The 410 superior performance of Llama3-8B over its 3B 411 variant can be attributed to its enhanced capacity 412 for maintaining feature relationships across layers 413 while preserving key compositional information. 414 415 While larger models excel in standard tasks (see Appendix E.1), they exhibit a greater reliance on 416 the identification of intrinsic features in the early 417 *layers*. We find that phrasal-level CAP substantially 418 impacts Gemma-2B and Llama models, suggesting 419 a heavy dependence on layer-wise information gain, 420 where they separate features in an uncorrelated and 421 highly distinct manner. While this aids in identify-422 ing complex feature patterns, it also makes them 423 more vulnerable to contextual noise-a weakness 494 425 that threatens their robustness and integrity. Notably, Qwen models outperform Llama and Gemma 426 despite similar parameter counts, likely due to byte-427 level BPE tokenisation and multilingual training, 428 which enhance compositional stability, whereas 429 Llama's expanded BPE and Gemma's Sentence-430 Piece prioritise efficiency over phrase retention, 431 increasing vulnerability to CAP interventions. 432

Activation abstraction vs the information loss. 433 Table 1 reveals significant variations in aggrega-434 tion function performance across sample models 435 for the IDM task (see Appendix E.3 for the rest 436 of the models and tasks results). The Max aggre-437 438 gation shows the most dramatic impact. This finding supports our argument that these models tend 439 to distribute information in a fragmented manner, 440 lacking the integration of compositional (lexical 441 and semantic) information across tokens and con-442

tiguous layers. The Mean aggregation provides 443 more balanced results, though performance drops 444 still indicate absence of consistent compositional 445 mechanisms. This issue becomes more pronounced 446 in token-phrases experiments (Figure 2). The Sum 447 aggregation consistently outperformed other meth-448 ods, with Mean aggregation following closely be-449 hind, particularly in original models. The Sum 450 aggregation reflects the cumulative effect of aggre-451 gating tokens into larger segments, reinforcing our 452 earlier conclusion. Instead of progressively build-453 ing semantic information across layers, the models 454 exhibit cumulative information loss, particularly 455 when interventions occur in early layers. 456

Fine-tuning enhances recovery capabilities across models. Figure 2 (d-f) demonstrates improved performance maintenance post-fine-tuning across all model families, with strongest gains in 75%-100% layer positions. SP tasks showed maximum benefit, attributed to high task specificity and minimal activation reduction under CAP. Max aggregation displayed the greatest improvement postfine-tuning, likely due to enhanced retention of key information. For instance, Gemma-2B's accuracy drop decreased from 97.91% to 57.65% in the 1% layer, while Qwen-3B improved from 7.23% to 3.65% in the 75% layer. Mean aggregation benefits were also substantial in smaller models, with Gemma-2B's 75% layer drop reducing from 31.03% to 15.00%. The Qwen family showed consistent improvements across all aggregation types, though smaller models like GPT2-large demonstrated minimal gains, suggesting potential overfitting. Notably, larger models like Llama3-8B showed minimal gains from fine-tuning in IDM tasks, indicating that standard fine-tuning objectives may not directly enhance compositional robustness. Although fine-tuning strengthens models' resilience under CAP, it does not fully resolve the challenge of forming stable compositional semantic representations, highlighting an architectural limitation in current transformer models.

# 5 Information Gain & Token Mutual Information

The empirical findings can be explained by looking at the autoregressive next-token objective of a transformer model from an information theoretical standpoint: examining the relationship between each generated token Y to the input token representations  $R_l(X)$  of each layer l, in terms

Figure 2: Average grouped accuracy of CAP across different aggregation functions for normalised layer positions (0%-100%) is shown for word-level CAP (TW) and phrasal-level CAP (TP). Sub-figures (a)-(c) illustrate the CAP effect on the original (Org) models, while sub-figures (d)-(f) show its impact on the fine-tuned (FT) models. Fine-tuning consistently improves performance, particularly in the middle to late layers (25%-100%), while early layers (0%-25%) show more variability and lower accuracy across models.

of Information Gain  $IG_{Y,R_l(X)}$ , and the aggregation of a pair of input token representations  $R_l(X_i), R_l(X_j)$  in terms of their Mutual Information  $I(R_l(X_i), R_l(X_j))$ .

 $IG_{Y,R_l(X)}$  quantifies the amount of information gained about the predicted token Y from the observation of the  $R_l(X)$ , for which the expectation is the mutual information  $I(Y, R_l(X))$  of Y and  $R_l(X)$ , which is equivalent to the reduction in entropy of Y achieved by learning the state of  $R_l(X)$ :  $IG_{Y,R_l(X)}(Y,r) = H(Y) - H(Y|r)$ .

During training,  $R_l(X)$  will be adjusted in a way that reduces the uncertainty about Y, meaning it will promote the maximisation of  $IG_{Y,R_l(X)}$  for any given layer l, which can be expressed as:

$$IG_{Y,X} = max(\sum_{l} IG_{Y,R_{l}(X)})$$
(5)

where  $IG_{Y,X}$  represents the information gain of Y w.r.t. input token X.

When looking at two input tokens  $X_i, X_j$ , the higher the mutual information  $I(R_l(X_i), R_l(X_j))$ is, the lower the impact that aggregating  $R_l(X_i)$ and  $R_l(X_j)$  would have over  $IG_{Y,X}$ , as those variables share more of the same information. Intuitively, that would apply to linguistic composition, e.g., tokens that form a word and thus have a stronger dependence when observed together. However, as the model's ability to predict Y is contingent on the accumulated information of all layers, and Equation 5 is independent of layer order, there is an intrinsic incentive to delay the aggregation of information (to later layers), as

$$IG_{R_{l_p}(X),R_{l_q}(X)} < IG_{R_{l_p}(X),R_{l_r}(X)}, \quad \forall p < q < r,$$
(6)

where p, q and r are layer indices, i.e., subsequent layers have more information about the inputs than previous ones. This can be explained in that optimising Equation 5 can be achieved by retaining at each  $R_{l_n}(X)$  only the necessary information to maximise  $\sum_{i,j} IG_{R_{l_q}(X_i),MHA(R_{l_p}(X_j))}$ , where  $MHA(R_{l_n}(X_i))$  is the multi-head attention weighted representation. Such an objective implies minimising the mutual information  $I(R_{l_n}(X_i), R_{l_n}(X_i))$ , i.e., reducing redundancy across tokens from the same layer. Therefore, token dependencies will tend to be modelled by aggregation paths spanning multiple layers, with more layers allowing for more complex and longer paths. This is in line with the findings of Mechanistic Interpretability studies (Elhage et al., 2021; Conmy et al., 2023). Equation 6 also implies that the earlier an aggregation is done, the larger the impact it will have on  $IG_{Y,X}$ , which explains the empirical results. The effects of  $I(R_l(X_i), R_l(X_i))$  on LLMs are further compounded by the tokenisation

objective (e.g., BPE, WordPiece), which *minimises*  $I(X_i, X_j)$ , i.e., token redundancy, as a means of reducing the vocabulary size, leading to longer aggregation paths.

#### 6 Related work

Compositionality, the principle that the meaning of complex expressions is derived from their parts and structure, is foundational in linguistics, cognitive science, and AI (Fodor, 1975; Montague and Thomason, 1975; Tull et al., 2024). In neural models, compositionality enables generalisation and interpretability, yet remains difficult to diagnose and enforce (Donatelli and Koller, 2023). Several studies investigate how and where compositional representations emerge in transformer models. Carvalho et al. (2025) observed similar effects in adjectivenoun phrase probing, while Haslett (2024) found that models struggle to segment or represent morphemes, especially in non-Latin scripts, suggesting breakdowns in both form and meaning composition. The logit lens (Nostalgebraist, 2020) demonstrated that transformers build predictions progressively where early layers make initial guesses and deeper layers refine guesses with broader context. (Dai et al., 2022) show feed-forward layers act as key-value memories, combining information for complex predictions. MEMIT (Meng et al., 2023) and PMET (Li et al., 2025) show how controlled inferences can be built by manipulating models' components. Some nuance emerges in later-layer behaviours. DecompX (Modarressi et al., 2023) traced token representations layer-by-layer and observed partial shifts toward integration. Yu and Ettinger (2020) tested model encoding and found that transformers mainly encode individual word content rather than true phrase-level meaning. While some models appear more compositional under certain conditions, general trends remain unclear. For example, Dankers et al. (2022) demonstrate that models can show unexpectedly high or low compositionality depending on the data and task, suggesting exposure and framing affect outcomes as much as architecture. Petty et al. (2024) show that deeper Transformers tend to generalise more compositionally than shallower ones, though the benefits diminish beyond a certain depth. This highlights that architectural depth, not just scale, may shape compositional ability, though with diminishing returns. In multi-step reasoning tasks, models often fall back on shallow pattern matching rather than

true decomposition (Dziri et al., 2023).

Prior work has primarily relied on synthetic tasks to assess compositional generalisation, focusing on properties such as systematicity, productivity, and substitutivity (Hupkes et al., 2020; Lake and Baroni, 2018), these setups often abstract away from the complexities of natural language. More recent studies using natural data are often limited to small domains such as semantic parsing or machine translation (Lake and Baroni, 2018; Kim and Linzen, 2020), and typically lack insight into internal representations.

In contrast to prior works focused on final outputs or synthetic tasks, CAP is a method for probing compositional structure within LLMs using real inputs. It intervenes directly on hidden activations, merging token-level representations into word- or phrase-level constituents at various depths. This allows us to evaluate where semantic composition occurs and how robust LLMs to structured perturbations. Unlike surface-level probes, CAP provides a targeted, activation-level lens on how meaning is constructed and distributed across model layers and linguistic units.

### 7 Conclusion

This work systematically analyses the robustness of transformer-based LLMs to compositional perturbations. Motivated by studies highlighting an unexpected gap between linguistic compositionality and LLM representations, we characterised the impact of compositional aggregation at each inference step and provided an information-theoretical explanation. Our findings indicate a pattern where token dependencies are modelled by aggregation paths spanning multiple layers, and complex token structure learning comes at the cost of higher sensitivity to perturbations at inputs and earlier layers. Based on the relation between information gain from input to predicted token and mutual information between token representations, we postulate that compositional semantic representations cannot be isolated to any particular (intermediate) stage of a standard transformer model. These insights suggest that future compositional-aware models should explore specialised architectures or training objectives. Natural extensions include analysing encoder-based and encoder-decoder transformers and investigating final token representations to further understand internal compositional mechanisms.

### 645 Limitations

Several limitations are acknowledged in our paper. First, the WordNet dataset may not fully represent 647 language diversity across all domains. Second, the employed transformer models are decoder-based only and could be subject to biases from their training data. Third, our findings depend on the Benepar parsing model, which may introduce inaccuracies in linguistic analysis. Additionally, while our tasks provide an indirect signal of meaning preservation, incorporating explicit reconstruction tasks in future 655 work could offer complementary insight into how CAP affects the retention of input-level information. Finally, the applicability of our results to other languages has not been tested. Expanding CAP to multilingual settings and testing with alternative parsers or models trained with different positional encodings would further validate the generality of our findings.

#### Ethical Statement

The proposed framework aims to have a positive impact on improving the critical understanding of the mechanisms involved in language interpretation in transformers. A more complete understanding of these mechanisms requires coordination with other interpretability methods.

#### A Compositionality and Localisation

The concept of linguistic compositionality has evolved from its origins in Frege's work (Frege, 1892), which started conceptualising the notion that the meaning of a complex expression is determined by its constituent parts and their syntactic arrangement. This principle was formalised by Montague (Montague, 1970b,a), who applied mathematical rigour to natural language semantics, thereby reinforcing the compositional approach within formal semantics. Linguistic phenomena such as idioms, context-dependence, and metaphor, which seemed to violate compositionality, prompted debates on its universality (Katz and Postal, 1963; Jackendoff, 1997), with theoretical accounts evolving to integrate these phenomena, leading to a more nuanced understanding that balances strict compositional rules with allowances for non-compositional elements (Partee, 1984).

While the syntactic-logical connection entailed by formal models is not assumed to be induced by neural language models, there is a common assumption that those models should entail a syntactic compositionality function, which allows for a systematic model for meaning composition, i.e., that the syntactic structure of a complex expression s is significantly determined by the syntactic properties of its constituent parts and the rules used to combine them. Formally, for any sentence s, its syntactic properties can be defined as a function f of the syntactic properties of its immediate constituents  $s_1, s_2, \ldots, s_n$  and the syntactic operations applied:

$$Syntax(s) = f (Syntax(s_1), Syntax(s_2), \dots, Syntax(s_n), Rules)$$
(7)

Within the context of distributed representations, a meaning representation can be factored into its syntactic and content (term embedding) components. A compositional distributional semantic 893 model merges syntactic compositionality with distributional semantics by representing token meanings as vectors (token embeddings) in a continuous 897 semantic space and combining them according to syntactic structure. Formally, each token t is as-898 sociated with a vector  $\mathbf{v}_t \in \mathbb{R}^n$  that captures its semantic content based on distributional informa-900 tion. 901

For a complex syntactic expression s composed of constituents  $s_1, s_2, \ldots, s_n$ , the semantic representation  $\mathbf{v}_s$  is computed using a compositional function f that integrates both the vectors of the constituents and the syntactic operations applied:

$$\mathbf{v}_{s} = f\left(\mathbf{v}_{s_{1}}, \mathbf{v}_{s_{2}}, \dots, \mathbf{v}_{s_{n}}, \text{Syntactic structure}\right)$$
(8)

This function f is designed to reflect syntactic compositionality by structurally combining the embeddings of the constituents according to the syntactic rules governing their combination.

In the context of a specific transformer-based LM model implementing an interpretation function of an input s, the question which is central to this work is whether the contiguous composition of tokens is reflected within the structure of the transformer-based LMs and its constituent parts, layers  $l_0...l_n$ , multi-head attention, feedforward layers and residual connections, i.e. whether the representations  $\mathbf{h}_i^{(k)}$  at each layer  $l_k$  explicitly encode the composition of contiguous tokens  $t_i, t_{i+1}$ , and how the model's components contribute to this encoding.

#### **B** Elaborations on Experimental Setup

#### **B.1** Downstream Task Definitions

The tasks selected for this study are designed to evaluate the effects of compositional aggregation, focusing on tasks that are strictly dependent on input tokens and their compositional semantics while minimising variability. Each task produces a singletoken output, and predictions are considered correct if they exactly match the target token. The following are the formal definitions for each task.

**Inverse Definition Modelling (IDM):** The *IDM* task involves predicting a term T based on a given natural language definition D. Let  $D = \{d_1, d_2, \ldots, d_n\}$  represent the sequence of tokens constituting the definition. The goal is to generate the corresponding term T, where:

$$T = \arg\max_{t \in \mathcal{V}} P(t \mid D) \tag{9}$$

Here,  $\mathcal{V}$  is the vocabulary of possible terms, and t is a candidate term. A prediction is correct if the term T exactly matches the target term. The task prompt used for IDM was structured as follows:

general-purpose vocabulary and does not target specific demographic groups or domains. Definitions were cleaned using typical preprocessing techniques, such as removing special characters, punctuation, and extra spaces, and removing parenthesised content when necessary. The dataset was initially split 80-20, with 20% used for training. The remaining 80% was then split 90-10, with 10% for validation and 90% for testing. The test dataset was filtered to retain only single-token predictions matching each model's tokenisation. Table 2 shows the test dataset sizes used for each task and model, including inverse dictionary modelling (IDM), synonym prediction (SP), and hypernym prediction (HP).

#### **B.3 Model Specifications and Fine-tuning Parameters**

Table 3 provides a comparative overview of various 1009 Transformer models used in this study. We used 1010 GPT2 models (released under the Modified MIT 1011 License), Gemma-2B (released under the Gemma 1012 Terms of Use), Llama3 models (released under the 1013 Meta Llama 3 Community License), and Qwen 1014 models (released under Apache License 2.0). The 1015 used models were mainly pre-trained on English 1016

Model		Original			Fine-tuned	l
Widdei	IDM	SP	HP	IDM	SP	HP

Table 4: Baseline performance of various models on three tasks: (inverse dictionary modelling) IDM, synonym prediction (SP), and hypernym prediction (HP). The values represent the accuracy of each model's original and fine-tuned versions.

data, with Qwen and LLama models providing 1017 additional multilingual support, which is English, 1018 German, French, Italian, Portuguese, Hindi, Span-1019 ish, and Thai for LLama, and more than 10 lan-1020 guages, including Chinese, English, French, Span-1021 ish, Portuguese, Russian, Arabic, Japanese, Korean, Vietnamese, Thai, and Indonesian for Qwen. All 1023 models were used for research purposes, specifi-1024 cally for language modelling and text generation 1025 in English, aligning with their intended usage. The 1026 models differ in their number of parameters, layers, 1027 heads, and feedforward (FF) dimensions. The num-1028 ber of parameters ranges from 85M for GPT2-small 1029 to 7.8B for LLama3-8B. The activation functions and FF dimensions also highlight variations in the 1031 internal processing architecture, influencing the 1032 models' performance across different tasks. In ad-1033 dition to these architectural differences, the models 1034 were fine-tuned using a consistent set of hyperpa-1035 rameters. The fine-tuning process spanned over 1036 three training epochs with a batch size of 16. The 1037 learning rate was set to 5e-5, while a weight decay 1038 of 0.01 was applied to prevent overfitting. Training logs were generated every 200 steps, with model 1040 checkpoints saved every 1000 steps, but limited to 1041 retaining only one checkpoint to manage storage efficiently. The evaluation strategy during fine-tuning 1043 was set to evaluate at the end of each epoch, and 1044 similarly, the model was saved at the end of each 1045 epoch as well. 1046

#### B.4 Handling of Sequence Reduction and Positional Encoding in CAP

1048

1049

1050

1051

1052

1054

CAP reduces the number of token-level activations from the original input length K to a shorter grouped sequence length G, by merging activations corresponding to word-level or phrase-level constituents. This reduction is applied post-token embedding and affects intermediate activations within the transformer, specifically the outputs of residual1055blocks or their internal components (e.g., attention1056or feedforward sublayers). From the point of CAP1057application onward, the model processes a reduced-1058length sequence of size G. This operation does not1059alter the model's input embeddings or positional1060encodings.1061

1105

Effect of Positional Encoding Schemes. The impact of this reduction depends on the positional encoding strategy used by the model: (i) GPT2 models use Sinusoidal positional embeddings, where each position index corresponds to a unique learned embedding. While CAP does not alter these embeddings directly, reducing the sequence length at intermediate layers can introduce misalignment between positional indices and semantic content. This may disrupt downstream attention or feedforward computations that assume consistent positional context; (ii) LLaMA, Qwen, and Gemma models use rotary positional encodings (RoPE), which encode position relationally through rotation in embedding space. These relative encodings are more robust to changes in sequence length, and CAP has a milder impact on positional semantics in these models. Nevertheless, changes in sequence structure may still affect how models integrate cross-token context.

Although CAP does not interfere with the model's input or positional embedding layer, it alters the spatial structure of activations mid-forward pass. This may influence how transformers aggregate information across positions, especially in models with absolute position encoding. Nevertheless, we did not observe severe performance degradation in those models compared to others. We acknowledge this as a potential contributing factor to the observed degradation under CAP and consider it an important area for future study.

Namely, Embedding-level analysis represents a promising direction for future exploration. Although this work evaluates a wide range of models with differing positional encoding schemes, we acknowledge the need for more targeted analysis of how CAP interacts with these embeddings. In particular, it would be valuable to quantify the impact of CAP under controlled conditions that isolate embedding effects. For instance, experiments using fixed or masked positional encodings, or applying CAP to models trained from scratch with alternative positional schemes, could help disentangle the influence of compositional pooling from that of

1107

#### C Token Reduction Analysis

Table 5 presents an analysis of activation reduc-1108 tion percentages across different LLMs, particu-1109 larly for the token-to-words case. In this context, 1110 the mean represents the average reduction percent-1111 ages across samples, while the standard deviation 1112 indicates the variability of these reductions. While 1113 models within a family (e.g., Qwen) share the same 1114 tokeniser and vocabulary, the reduction percentages 1115 still vary across tasks (e.g., SP vs. HP) because dif-1116 ferent tasks involve input definitions or prompts 1117 with different average sentence lengths and syn-1118 tactic complexity, which in turn affect how many 1119 groupings are formed under CAP. In other words, 1120 although the tokeniser is fixed, the number and 1121 size of groupable units (e.g., multi-token words or 1122 phrases) are input-dependent. The purpose is to as-1123 sess whether token reduction across models would 1124 highly influence the results of CAP. 1125

1126Token reduction is a factor but not the sole de-1127terminant of performance degradation. The1128results presented in Tables 9, 10, and 11 indicate1129that while token reduction percentage influences1130performance degradation, it is not the sole deter-1131mining factor. Several key observations support

this conclusion, which is discussed below.

First, we observe that higher token reduction 1133 does not always lead to a greater performance 1134 drop. For instance, models such as Gemma-2B and 1135 Llama3-8B exhibit high token reduction percent-1136 ages (Table 5), yet their performance degradation 1137 varies significantly across tasks and layer positions. 1138 Also, despite lower token reduction percentages, 1139 the models Qwen 0.5B and GPT2-small still show 1140 substantial accuracy drops, particularly in early lay-1141 ers in the SP and HP tasks. Second, model size and 1142 depth influence degradation, as evident in the larger 1143 models (e.g., Llama3-8B, Gemma-2B) exhibiting 1144 greater fragility to CAP interventions, particularly 1145 in early layers (1% and 25%). Third, as discussed 1146 in the paper, layer-specific variability suggests hi-1147 erarchical processing differences. Early-layer CAP 1148 interventions cause severe accuracy drops in large 1149 models but have a less pronounced effect in smaller 1150 models, suggesting that deeper architectures defer 1151 compositional integration to later layers. Further, 1152 fine-tuning reduces degradation in later layers (75% 1153 and 100%), implying that learned representations 1154 in deeper layers mitigate the effects of early pertur-1155 bations. Finally, architectural differences influence 1156 sensitivity. We observe that higher MLP dimen-1157 sions (e.g., Llama3-8B: 14,336 vs. GPT2-small: 1158 3,072) correlate with greater vulnerability to CAP 1159 perturbations, likely due to increased parameter 1160 redundancy and disruption of the key-value recall 1161 mechanism in MLPs (Meng et al., 2022). 1162

1174

1175

1176

1177

1178

While the token reduction percentage contributes to performance degradation, it is insufficient to fully explain the observed variations. Task nature, model size, layer depth, activation functions, and MLP dimensions collectively influence the robustness of CAP interventions. Larger, deeper models demonstrate greater sensitivity to early perturbations, while fine-tuning helps recover performance in later layers. These findings suggest that effective compositional representations in LLMs are distributed rather than localised, requiring specialised architectures or training objectives to improve robustness.

## D Evaluating Parsing Accuracy and Addressing the Impact of Benepar Parser Errors

A key potential bias in our results comes from the1179reliance on the constituency parser for token-to-1180phrase experiments. Inaccuracies in parsing may1181

Figure 3: Average grouped accuracy of CAP across different aggregation functions for normalised layer positions (0%-100%) is shown for word-level CAP (TW) and phrasal-level CAP (TP). Sub-figures (a)-(c) illustrate the CAP effect on the original (Org) models, while sub-figures (d)-(f) show its impact on the fine-tuned (FT) models. Fine-tuning consistently improves performance, particularly in the middle to late layers (25%-100%), while early layers (0%-25%) show more variability and lower accuracy across models.

1182 distort the results of CAP. To address this, we report the chosen parser's accuracy by testing it on 1183 the Stanford Sentiment Treebank (SST) dataset, a 1184 dataset that offers golden labels for parsing. We 1185 aim to alleviate concerns about the parser's impact 1186 on our findings by showcasing its accuracy on the 1187 SST dataset. The parser evaluation was conducted 1188 as follows: 1189

Dataset. A subset of 1,000 randomly sampled 1190 sentences from the test split of the SST dataset was 1191 used for the analysis. The Stanford Sentiment Tree-1192 bank (SST) provides annotated constituency labels, 1193 which serve as the golden labels for comparison 1194 with parser outputs. While WordNet definitions of-1195 fer rich semantic information, they lack annotated 1196 golden constituency labels, making direct parser 1197 validation infeasible. The use of SST's annotations 1198 enables reliable parser evaluation and indirectly 1199 supports the validation of the parsing correctness 1200 for WordNet definitions, provided they follow standard syntactic structures. 1202

1203**Parser.** The Benepar parser was employed for1204parsing sentences due to its strong performance1205in constituency parsing tasks. Benepar is widely

recognised for its robustness and ability to handle diverse syntactic structures. For this evaluation, the constituency structures generated by Benepar were directly compared against SST's golden annotations to assess its parsing accuracy. 1206

1207

1208

1209

1210

**Evaluation metrics.** The parser's performance 1211 was evaluated using the following metrics: (i) Preci-1212 sion: Proportion of correctly predicted constituents 1213 out of all predicted constituents; (ii) Recall: Pro-1214 portion of correctly predicted constituents out of all 1215 ground truth constituents; (iii) F1-Score: Harmonic 1216 mean of precision and recall, providing an overall 1217 performance measure; and (iv) Accuracy: Percent-1218 age of sentences where the predicted constituency structure fully matches the ground truth. 1220

Results robustness. To ensure robustness and 1221 consistency, the evaluation was repeated across five 1222 different random seeds. This allowed for an assess-1223 ment of variability in performance across multiple 1224 subsets of the dataset. Additionally, constituents 1225 were evaluated at hierarchical levels-such as root 1226 level, phrase level, and token level-to analyse 1227 parsing performance across varying syntactic granularities. 1229

**Results.** The evaluation yielded the following averaged metrics across five seeds for the default level of parsing (Level 1, the immediate children of the root node):

Metric	Mean ± Std
Precision	$0.956 \pm 0.001$
Recall	$0.956 \pm 0.001$
F1-Score	$0.956 \pm 0.001$
Accuracy	$0.956 \pm 0.001$

Table 6: Aggregated evaluation metrics for Level 1 constituents using the Benepar parser, averaged across five seeds.

**Interpretation.** The results demonstrate consistently high parsing accuracy across all evaluation metrics, with minimal variability (as indicated by the low standard deviation). These findings validate the Benepar parser's reliability for parsing Level 1 constituents, which form the backbone of sentence structure. Consequently, the parser's impact on CAP results is minimal, ensuring robustness and validity of our conclusions.

#### E **Detailed Performance Evaluation and** Results

#### **Baseline Performance E**.1

Table 4 summarises the baseline performance of the models used in this paper on the three tasks. The results include the accuracy of each model's original and FT versions on the test set described in Table 2. Fine-tuning generally improves performance, particularly in the larger models such as Gemma-2B and Llama3-8B, which show notable increases in accuracy in most tasks, except the IDM task.

#### **Qualitative Analysis of CAP-Induced E.2** Prediction Shifts.

Tables 7 and 8 present representative examples of predictions from multiple models across all the tasks, before and after CAP is applied. These examples are drawn from inputs that the model originally predicted correctly, allowing us to isolate the effects of CAP perturbations without confounding them with unrelated model failures. Each example specifies the CAP layer, CAP type (token-to-word or token-to-phrase), and the model involved. Table 7 focuses on predictions made by original (nonfine-tuned) models, while Table 8 includes outputs from fine-tuned variants. Observed shifts include truncation of multi-token terms (e.g., "diary"

 $\rightarrow$  "di"), polarity inversion (e.g., "plain"  $\rightarrow$  "orna-1270 ment"), loss of abstraction ("polygon"  $\rightarrow$  "plane"), 1271 and domain misalignment (e.g., "tree"  $\rightarrow$  "street"). 1272

These qualitative differences provide interpretability insights that complement the aggregate metrics reported earlier. They reveal how CAP affects not only performance but the nature of model outputs, especially in terms of semantic generalisation, abstraction shifts, and lexical precision. While we do not observe a uniform trend across layers or model families, TP-CAP consistently induces more severe semantic degradation. This suggests that as model capacity increases, internal representations may become more sensitive to disruptions from externally imposed syntactic structures, potentially due, as argued in the main paper, to a stronger reliance on learned token-level dependencies that diverge from higher-level compositional groupings. This analysis highlights the nature of semantic and lexical shifts induced by CAP, reinforcing the need for future task-specific fine-tuning strategies that improve robustness to structured representation pooling.

#### **E.3 Comprehensive CAP Results for All Models and Tasks**

Figure 3 and Tables 9-13, and 14 present the reduction in accuracy when applying word-level and phrasal CAP, respectively, across models and the three tasks: IDM, SP, and HP. The results of phrasal-level CAP for Gemma-2B and Llama3-8B are not reported due to the severe degradation in model performance under these conditions, rendering the outputs effectively unusable.

Let  $A_o$  represent the original accuracy and  $A_c$ represent the accuracy after applying CAP. The reported drop in accuracy,  $\Delta A$ , is calculated as:

$$\Delta A = A_o - A_c \tag{12}$$

This  $\Delta A$  value is expressed in percentage points. 1307 For example,  $\Delta A = 40$  indicates that the model's 1308 accuracy has decreased by 40 percentage points 1309 from its original performance, which could repre-1310 sent a change from  $A_o = 100\%$  to  $A_c = 60\%$ , or any other pair of accuracies with a 40 percentage 1312 point difference. The tables report  $\Delta A$  for differ-1313 ent layer positions (1%, 25%, 75%, and 100%) in 1314 both Original and Fine-tuned settings, using three 1315 CAP protocols: Max, Mean, and Sum. This representation allows for a direct comparison of CAP's 1317 impact across different models and tasks, indepen-1318 dent of their baseline performance levels. 1319

Table 13: Performance drop (in percentage points) for GPT2-small, GPT2-medium, and GPT2-large models after applying phrasal-level CAP across three tasks: Inverse Dictionary Modelling (IDM), Synonym Prediction (SP), and Hypernym Prediction (HP). Results are reported for different layer positions (1%, 25%, 75%, and 100%) in both Original and Fine-tuned settings, using three CAP protocols: Max, Mean, and Sum. Results for Gemma-2B and Llama3-8B are omitted due to severe performance degradation under phrasal-level CAP.

Model	Layer Position	Original			Fine-tuned		
		Max	Mean	Sum	Max	Mean	Sum
HP (Hypernym Prediction)							
GPT2-small	1%	99.40%	99.26%	47.24%	89.31%	89.86%	88.76%
	25%	99.31%	98.12%	46.38%	77.72%	73.12%	76.08%
