

# EFFECTS OF SCALE ON LANGUAGE MODEL ROBUSTNESS

Anonymous authors  
Paper under double-blind review

## ABSTRACT

Language models exhibit scaling laws, whereby increasing model and dataset size yield predictable decreases in negative log likelihood, unlocking a dazzling array of capabilities. At the same time, even the most capable systems are currently vulnerable to adversarial inputs such as jailbreaks and prompt injections, despite concerted efforts to make them robust. As compute becomes more accessible to both attackers and defenders, which side will benefit more from scale? Will safety-trained frontier models become robust against any but the strongest attacks, or will additional compute make attacks almost impossible to defend against?

We attempt to answer this question with a detailed study of robustness on language models spanning three orders of magnitude in parameter count. We find that increasing base model size alone does not consistently improve robustness. However, larger models benefit more from safety-training, and in particular better generalize from adversarial training to new attacks. We then study the attacker’s perspective, finding predictable improvement in attack success rate as attacker compute is increased against all models studied. Finally, we show that offense widens its advantage as both sides spend more on compute.

## 1 INTRODUCTION

Language models have demonstrated a range of impressive capabilities in tasks such as general language understanding (Hendrycks et al., 2021), graduate-level Q&A (Rein et al., 2023), and code generation (Chen et al., 2021). This growth in capabilities has fueled rapid deployment, with ChatGPT becoming one of the fastest-growing consumer applications in history (Hu, 2023). Language models are now increasingly integrated into larger systems, enabling them to take actions in the real world using external tools (OpenAI, 2023; Anthropic, 2024; Google, 2024) and to pursue long-term open-ended goals (Richards, 2024; Kinniment et al., 2024).

While the advent of language models enables many new tasks to be solved by AI, it also introduces novel classes of security vulnerabilities. A variety of adversarial prompts can bypass safety fine-tuning (Wei et al., 2023; Zou et al., 2023; Anil et al., 2024), unlocking harmful capabilities such as generating misinformation (Spitale et al., 2023; Chen & Shu, 2024). Users of LLM-driven applications are also at risk from attacks like indirect prompt injections (Abdelnabi et al., 2023) that exploit the underlying LLM without the user’s awareness or participation. As models become more capable, the risks from attacks will increase, with future models potentially able to assist with dangerous actions such as biological weapon development (Mouton et al., 2023). These concerns compound as models are given greater affordances to interact with the world (Sharkey et al., 2023).

Over a decade of research in adversarial robustness (Szegedy et al., 2014) has yet to find a way to reliably defend against adversarial attack, and attackers and defenders remain locked in a game of cat-and-mouse. Taking a step back from the specifics of this game today, what general trends can we identify to inform us about the future? In particular, how will increased access to compute—for both attackers and defenders—affect the robustness of frontier models?

Previous results tell an uncertain story. In computer vision, scaling unlabeled pretraining data (Hendrycks et al., 2019; Carmon et al., 2022; Alayrac et al., 2019) and model size (Xie & Yuille, 2019; Huang et al., 2023; Caballero et al., 2023) improve model robustness. In turn, scaling up language models has led to improved capabilities across a variety of settings (Hestness et al.,

2017; Wei et al., 2022; Radford et al., 2019). Ganguli et al. (2022) found a weak correlation between model size and better robustness to red-teaming attacks, though they only consider three model sizes, making it difficult to identify a clear trend. At the same time, recent years have seen the development of impressive adversarial attacks, which become stronger still when given access to more compute—whether by running the attack for more iterations (Zou et al., 2023; Sadasivan et al., 2024), or by using a larger model for automated red-teaming (Perez et al., 2022).

In this work, we conduct the first publicly available large-scale empirical investigation into scaling trends for the adversarial robustness of language models. These trends quantify attack scaling and defense scaling, and enable us to predict whether a world with more compute will help or hurt robustness (Garfinkel & Dafoe, 2021).

On the attack side, we find that attack success rate improves smoothly against both undefended and defended models as a function of attack compute spent. The picture is more complex for defense. We find that larger base models are not necessarily more robust than smaller models. However, larger models benefit more from safety training than do smaller models. In particular, larger models are better able to generalize robustness from adversarial training to a different threat model.

Finally, we turn our attention to the offense-defense balance as both sides scale up compute. We find that while increasing model size and performing adversarial training significantly improve robustness, it becomes relatively *less* expensive for attackers to achieve the same attack success rate at larger scale. Taking the IMDB task as an example, Figure 1 shows that as the defender spends more compute on adversarial training ( $x$ -axis), the attacker can increase their spending ( $y$ -axis) at a slower rate (slope less than 1) and still maintain the same attack success rate. Further, in absolute terms, attack costs approximately 3 orders of magnitude less than adversarial training, suggesting that defenders will need to spend increasingly more than attackers if they intend to maintain a low attack success rate.

## 2 RELATED WORK

Adversarial examples were first identified in image classifiers (Szegedy et al., 2014), and have since been found for systems performing image captioning (Xu et al., 2019; Zhang et al., 2020), speech recognition (Cisse et al., 2017; Alzantot et al., 2018; Schönherr et al., 2018), and reinforcement learning (Huang et al., 2017; Gleave et al., 2020; Ilahi et al., 2022).

Most recently, many qualitatively different vulnerabilities have been found in language models, from interpretable jailbreaks (Wei et al., 2023) to seemingly gibberish adversarial suffixes (Wallace et al., 2021; Zou et al., 2023). Methods such as perplexity filtering and paraphrasing defend against some of these attacks (Jain et al., 2023), but such defenses can often be bypassed by more sophisticated attacks (Zhu et al., 2023). Adversarial training can in theory be used against any attack, and can be scaled up or down depending on defender compute, so we use it as the basis for defending models in this study.

The determinants of adversarial robustness have been well-studied in computer vision (CV). One line of scholarship proposes a fundamental tradeoff between robustness and accuracy (Tsipras et al., 2019), positing that exploitable models are simply relying on non-robust features (Ilyas et al., 2019), which improve training performance but hurt robustness. Other work has emphasized what *improves*

Figure 1: Attack compute needed to achieve a 5% attack success rate vs. defense compute used for adversarial training on the IMDB task. A slope of 1 (dashed lines) corresponds to an attacker needing to double the attack compute in response to a doubling of defense compute. The slope is typically below 1, corresponding to an advantage for offense; see Section 6.

robustness. For example, scaling unlabeled pretraining data (Hendrycks et al., 2019; Carmon et al., 2022; Alayrac et al., 2019), model depth (Xie & Yuille, 2019) and model width (Huang et al., 2023) all improve CV adversarial robustness. However, other work shows that increasing scale alone will not fully solve CV adversarial robustness (Debenedetti et al., 2023; Bartoldson et al., 2024).

Language model scaling laws (Hestness et al., 2017; Rosenfeld et al., 2019; Kaplan et al., 2020; Hoffmann et al., 2022) have shown that increasing compute improves performance across many tasks and domains (Chen et al., 2021; Hernandez et al., 2021), leading some to surmise that “perhaps many capabilities simply lie on a spectrum that can be continuously unlocked with increasing scale” (Henighan et al., 2020). Yet we know scaling does not solve *all* problems—indeed, it makes some worse (Lin et al., 2022; McKenzie et al., 2023). There has been only limited work on scaling laws for adversarial robustness in language models, with mixed results. Larger models are shown to be generally harder to red-team in Ganguli et al. (2022), while Anil et al. (2024) find that in-context learning attacks are *more successful* on larger models with larger context windows. In turn, Yang et al. (2024) find some improvement to robustness with scale when using a substitution-based attack, though their attack sometimes significantly corrupts inputs. In this work, we systematically study effects of scale on language model robustness by varying model size, adversarial training, and attack strength across a variety of tasks.

### 3 EXPERIMENTAL METHODOLOGY

We study robustness of models spanning three orders of magnitude in size drawn from two families across six classification tasks and one generation task, under three attacks and multiple defenses.

**Metrics** We measure robustness by the *attack success rate*. For binary classification tasks this is simply the proportion of examples correctly classified by the model before attack that are incorrectly classified after attack.<sup>1</sup> For generative tasks, a direct definition is not possible as refusal cannot be programmatically checked. We therefore follow StrongREJECT (Souly et al., 2024) and evaluate model responses to harmful questions using an LLM-based judge. For comparability to classification tasks, we evaluate only on examples that the model refused in the pre-attack evaluation.

**Models** We primarily study the Pythia model suite (Biderman et al., 2023). Pythia was the most suitable open-weight model family for a systematic study as it provides many different models across three orders of magnitude in size, with comparable architectures, all trained on the same dataset. Specifically, we use the non-deduped Pythia model family which consists of 10 autoregressive language models ranging from 14M to 12B parameters, pre-trained on the Pile (Gao et al., 2020). To create classification models, we replace the unembedding matrix with a classification head. After this replacement, the Pythia models range from 7.6M to 11.6B parameters.<sup>2</sup>

In addition to Pythia, we run on the more recent Qwen2.5 family of language models (Qwen Team, 2024). The Qwen2.5 family contains multilingual base and instruction-tuned models ranging from 0.5B to 72B. We use a subset of these models, ranging from 0.5B to 7B for our classification tasks and from 0.5B to 14B for our generative task. For the base models, as with Pythia, we create classification models by replacing the unembedding matrix with a classification head.

We finetune all classification models for three epochs on a task dataset consisting of 20,000 examples, using a linear learning rate schedule that decays from  $1e-5$  to 0. See Table 1 for worst-case accuracies for the smallest and largest models of each family after finetuning; Figures 8 and 9 show accuracies for all models sizes in both families. We find that even the smallest 7.6M parameter Pythia model achieves high accuracy on most classification tasks, enabling us to study robustness across a significantly wider scale than is possible in generative tasks.

**Tasks** We consider six classification tasks and one generation task, spanning several domains.

<sup>1</sup>We assume that the attack does not change the ground truth label of the datapoint. This is guaranteed by construction for our procedurally generated tasks, and was manually validated on a random sample of datapoints in other tasks. For examples of attacked datapoints, see Appendix A.

<sup>2</sup>Models were loaded as `AutoModelForSequenceClassification` in HuggingFace Transformers. We report the actual parameter count of the classification model, not that of the original pretrained model.

We use two standard natural language classification tasks: Spam, whether an email is spam (Metsis et al., 2006), and IMDB, whether a movie review is positive (Maas et al., 2011). These tasks are chosen to test natural language understanding and are relatively easy.

We hand-design two procedurally generated tasks: PasswordMatch compares if two strings in the prompt are equal, inspired by TensorTrust (Toyer et al., 2023); WordLength compares if the first word in a prompt is longer than the second, inspired by the RuLES dataset (Mu et al., 2023). These tasks are chosen to have a more “algorithmic” flavor based on comparing different parts of the input, and are also relatively easy.

We adapt the Bai et al. (2022) dataset of preference comparisons into two classification tasks, Helpful and Harmless. These are challenging tasks of the kind routinely used to align frontier models.

For generation, we use data from the StrongREJECT task (Souly et al., 2024). In particular, we measure the refusal rate of the model on harmful prompts, with the attack considered to have succeeded if a GPT-4o judge (gpt-4o-2024-05-13) considers the model to have answered the question.

We provide example datapoints and details about the datasets in Appendix A. Due to computational limitations, we performed some evaluations on only a subset of tasks.

**Attacks** We consider three adversarial attacks, each of which appends an adversarial suffix of  $N$  tokens to the prompt: a baseline black-box RandomToken attack, the state-of-the-art white-box *greedy coordinate gradient* (GCG) attack (Zou et al., 2023), and the strong black-box BEAST attack (Sadasivan et al., 2024). We choose these attacks because they are straightforward yet powerful, enabling us to study general scaling behavior without overfitting to phenomena arising from more specifically targeted attack methods like those in Andriushchenko et al. (2024).

In the RandomToken baseline, the  $N = 10$  tokens are chosen uniformly at random from the model’s vocabulary. We evaluate the model on the attacked text, repeating the process with newly sampled  $N = 10$  random tokens (which replace the old ones) until the model is successfully attacked or an appointed budget for model calls is exhausted.

In GCG (Zou et al., 2023), the  $N = 10$  tokens are initialized arbitrarily and then greedily optimized over multiple rounds. In each round, the gradient of the loss function with respect to the attack tokens is computed. This gradient is used to compute a set of promising single-token modifications, from which the best candidate is used in the next round. To make this attack work in the classification setting, we minimize the cross-entropy loss between the predicted label and the target label. Importantly, we apply GCG to datapoints individually rather than optimizing a single attack across multiple prompts, leading to a very strong attack.

BEAST (Sadasivan et al., 2024) appends  $N = 25$  tokens, building up a suffix token-by-token. It maintains a beam of  $k = 7$  candidate suffixes. In each of its  $N$  iterations, the attack samples  $k$  next tokens for each candidate to generate  $k^2$  new candidates and forms the next beam out of the candidates achieving the lowest adversarial loss. In the reference implementation, the tokens are sampled from the victim model to keep their perplexity low, but since our victims are classification models we instead sample from a small base model. We use BEAST to see how well models can

Dataset	Min Acc.
Pythia 7.6M Parameters	
Spam	0.980
IMDB	0.861
PasswordMatch	0.995
WordLength	0.876
Helpful	0.609
Harmless	0.594
Pythia 11.6B Parameters	
Spam	0.990
IMDB	0.955
PasswordMatch	0.995
WordLength	0.960
Helpful	0.609
Harmless	0.688
Qwen2.5-0.5B (base)	
Spam	0.995
Harmless	0.668
Qwen2.5-14B (base)	
Spam	0.995
Harmless	0.710
Qwen2.5-0.5B-Instruct	
StrongREJECT	0.556
Qwen2.5-14B-Instruct	
StrongREJECT	0.981

Table 1: Minimum accuracies on clean data. On classification tasks, we finetune the Base model, and large and small models perform comparably. On the generative task, we use the Instruct model, and larger models are significantly more likely to refuse harmful questions.

Figure 2: Attack success rate ( $y$ -axis) of GCG against different model sizes ( $\log_{10}$  scale  $x$ -axis) of Pythia on six classification tasks (**left**) and Qwen2.5 on two classification tasks and a generative task, StrongREJECT (**right**). We plot the median over at least 3 random seeds and shade the region between the min and max. We used different attack strengths across tasks in order to avoid saturating at either 0% or 100% attack success rate, see Appendix C.2. We observe a noisy and task-dependent trend of larger models generally, but not always, achieving better robustness against the attack. See Figure 11 to see each task on its own plot for readability.

defend against a targeted black-box attack that cannot retrieve gradients, since this is closer to the threat model faced by proprietary frontier models exposed only through an API.

For more details about the attacks and hyperparameters used, see Appendix B.

## 4 SCALING TRENDS FOR FINETUNED CLASSIFIERS

We first study the robustness of models that have not undergone any safety training.

**Larger models are more robust on average.** Figure 2 shows the robustness of our finetuned models as a function of model size when attacked with the GCG attack. We observe a noisy and task-dependent trend. For the Pythia family (left), larger models are generally more robust than smaller models: for example, on the IMDB task, the attack achieves a median success rate of almost 100% against the 7.6M model, while it achieves less than 20% against the 12B parameter model. However, even among tasks where scale appears to help, we observe significant variability across model sizes and tasks. For example, in the Spam task, increasing parameter count over 50x from 123.7M (4th blue point from the left) up to 6.7B (3rd blue point from the right) results in a *higher* attack success rate. Furthermore, in the WordLength task, model size does not appear to confer any additional robustness at all. See Figure 10 for similar results with the RandomToken attack.

For the Qwen2.5 family (right), the trend is less pronounced, though this might be in part due to the limited breadth of model sizes. On classification tasks, robustness appears approximately constant across model sizes. On the generative StrongREJECT task, the trend is clear: larger models are consistently more robust. This is likely because the generative Qwen2.5 models we tested are from the Instruct family, and thus have undergone some safety training. Thus, we might expect these results to look more similar to the adversarially trained classification results in Section 5.

While increasing model scale improves adversarial robustness on most tasks, this trend is high-variance at best, and non-existent at worst. The effect from scale is also very weak: in early experiments, we found that even moderately increasing the number of attack iterations quickly saturated attack success rate near 100%, removing any clear scaling behavior.

### 4.1 ATTACK COMPUTE SCALING

**Attack success scales smoothly against finetuned models.** We now consider the attacker’s perspective: across different model sizes, how much additional compute does it take to increase attack success rate? Here we observe a clean scaling trend, whereby attack success rate smoothly improves

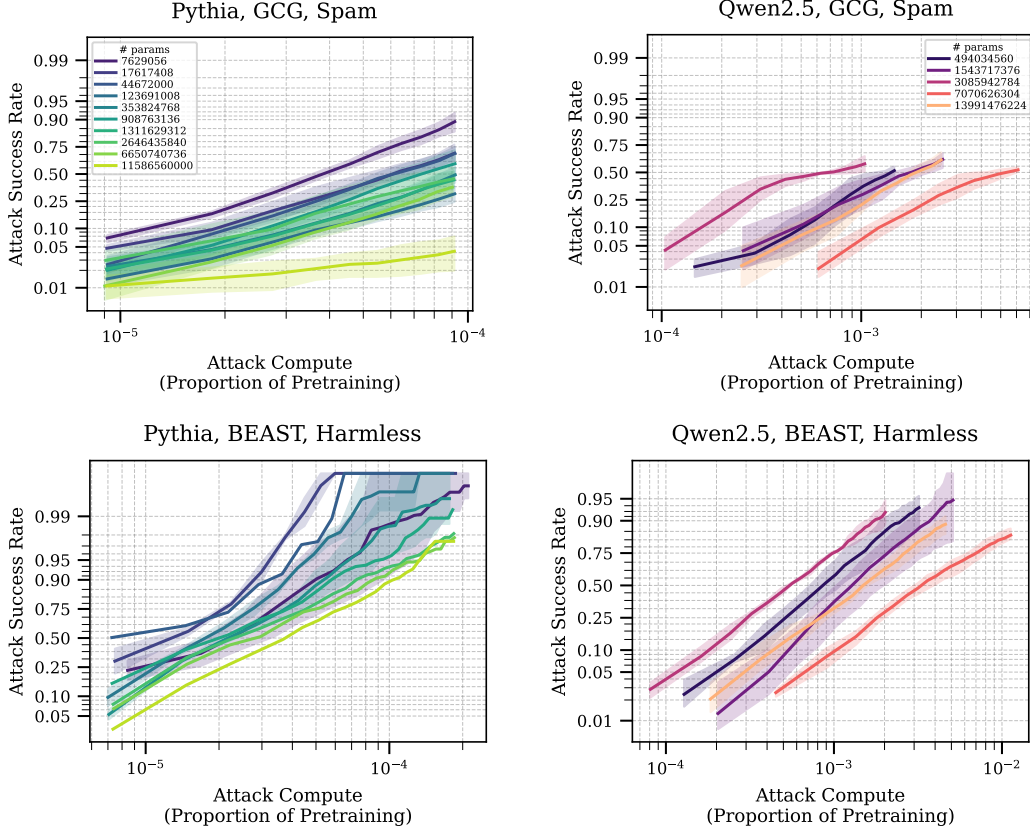

Figure 3: Attack success rate ( $\log_{10}$ -scale  $y$ -axis) of GCG (top) and BEAST (bottom) over different amounts of attacker compute expressed as a fraction of pretraining compute ( $\log_{10}$ -scale  $x$ -axis) against Pythia (left) and Qwen2.5 (right) models of different sizes (color) finetuned on Spam (top) and Harmless (bottom). On the Pythia models, we observe that attacks against larger models generally require more *relative* compute in order to reach comparable attack success rate than do attacks against smaller models, while the distinction between model sizes is less clear for Qwen2.5. See Appendix C for results on different combinations of models and tasks, and using the RandomToken attack. Note: the  $y$ -axes are on different scales, and the  $x$ -axes includes manual adjustment to account for a bug in our FLOP estimation code (see Appendix F).

with compute spent, across models, sizes, and attacks. In the Pythia family (left), we observe that larger models are more expensive to attack both in absolute terms and in *relative* terms, with the slopes of larger models being generally less than their smaller counterparts. The distinction between model sizes is much less clear in the Qwen2.5 family (right): across tasks and attacks, it appears that model size makes little difference in the relative cost of increasing attack success. We provide a deeper exploration of attack scaling in Appendix C.5.1, including a discussion of other tasks and the RandomToken attack. We also fit slopes to the attack success rate curves.

Fortunately for the defender, model size is not the only axis along which a defender can spend compute: it is common practice for a model to undergo extensive safety training before deployment, including by adversarially training on attacked examples. In the following section, we study how scale affects robustness of adversarially trained models.

## 5 SCALING TRENDS FOR ADVERSARIALY TRAINED CLASSIFIERS

Our adversarial training procedure is detailed in Algorithm 1. We adversarially train classification models ranging from 7.6M to 2.6B parameters for Pythia, and from 0.5B to 7B for Qwen2.5, starting from the finetuned models of Section 4. After adversarial training is complete, we evaluate the different checkpoints on an attacked validation dataset. We also monitor performance on a clean

**Algorithm 1** Adversarial Training**Require:** Clean training dataset  $D$ .

- 1: Initialize an empty pool of attacked examples,  $P \leftarrow \{\}$ .
- 2: **while** training not finished **do**
- 3:   Adversarially attack subset of  $D$ , adding the attacked examples to  $P$ .
- 4:   Train model on dataset constructed by sampling from  $D$  and  $P$ .
- 5:   Save model checkpoint for future evaluation.
- 6: **end while**

validation dataset to ensure the models maintain their high performance on the original task: see Figures 19 and 20 for reference. For full details of the adversarial training procedure, including choice of hyperparameters and an explanatory diagram, see Appendix D.

**Adversarial training quickly improves robustness.** Figure 22 shows that, for the Spam and IMDB tasks, models become more robust to adversarial attacks over the course of adversarial training. For example, in the Spam task, all but one of the finetuned (“Round 0”) models from Section 4 can be attacked more than 50% of the time, with the smallest three models above 75%. After just 5 rounds of adversarial training (at which point the model will have seen roughly 1000 adversarial examples), the attack success rate for all models has dropped below 10%. Larger models tend to be more sample efficient, attaining greater robustness with fewer rounds of adversarial training, with the largest three models at a 1% or lower attack success rate after 5 rounds. Robustness continues to improve over the course of subsequent rounds of adversarial training.

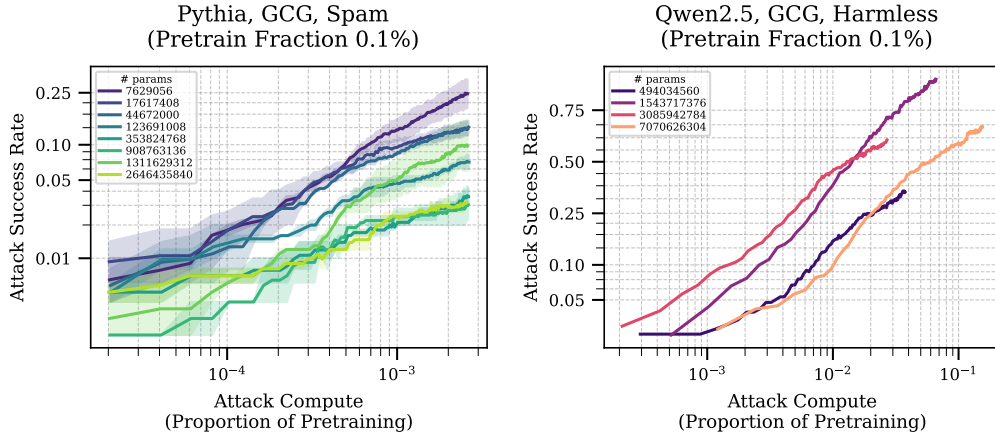

Figure 4: Attack success rate (logit<sub>10</sub>-scale  $y$ -axis) of up to 128 iterations ( $x$ -axis) of GCG against Pythia models on the Spam task (left) and against Qwen models on the Harmless task (right) after an amount of adversarial training corresponding to 0.1% of pretrain compute. As in the finetuned-only case, larger Pythia models are harder to attack than smaller Pythia models before adversarial training, and maintain that advantage over the course of adversarial training. In turn, for the Qwen family, there is little variation in robustness across models over the course of adversarial training.

**Attack success scales smoothly against adversarially trained models.** In Figure 4, we plot attack success rate as a function of the proportion of pretraining compute spent attacking, after the model has undergone different amounts of adversarial training. All models are much more robust after adversarial training using 0.1% of pretraining compute, and this benefit persists across a wide range of attack compute.

**Adversarial training is cost effective.** We find that adversarial training is a substantially more compute efficient way to increase robustness than scaling model size. Figure 2 showed inconsistent benefit across tasks from scaling model size alone. Even in the best case of IMDB, scaling pretraining compute (and thus model size) by 3000% only reduced the success rate of a fixed-strength GCG attack from 99% to 15%. By contrast, in Figure 5, we see that spending less than 2% of pretraining

compute on adversarial training is sufficient to achieve a greater reduction in adversarial attack success: from 95% to 2%.

In summary, we find that adversarial training improves robustness across tasks and model sizes, lessens the robustness gap between robustness of small and large models.

### 5.1 ROBUSTNESS TRANSFER

The effectiveness of adversarial training is promising, but our previous analysis misses one important point: in the real world, we often do not know beforehand which attack methods our model will be subjected to. To achieve real-world robustness, we need our defense to generalize to attacks that are not encountered during training. It is with this motivation in mind that we turn our attention to robustness transfer.

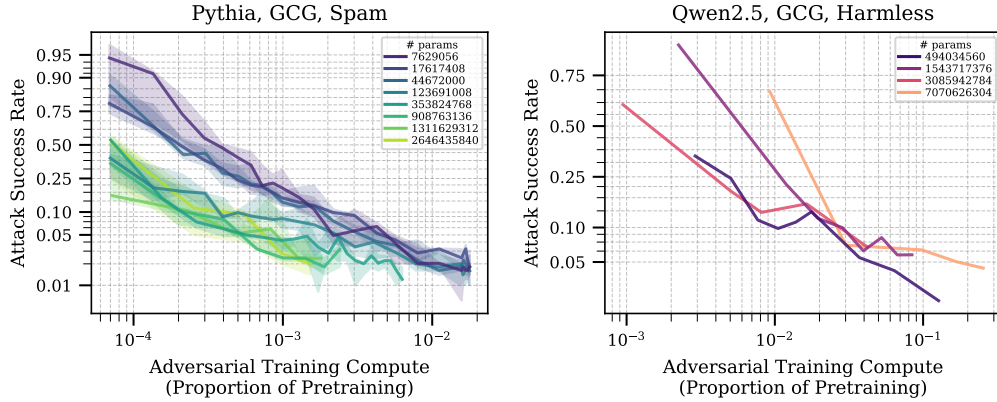

Figure 5: Transfer from adversarial training against 64-iteration GCG to evaluation against 128-iteration GCG. All model sizes are able to transfer to the stronger attack. For the Pythia family (**left**), larger models maintain their initial robustness advantage over the course of adversarial training, while the Qwen2.5 models (**right**) show less distinction between model sizes. In both families, the rate of improvement is similar across model sizes.

**Adversarial training generalizes to a stronger in-distribution attack.** Can adversarially trained models be robust to a stronger version of the same attack seen during training? Our models were adversarially trained against 64-iteration GCG, so to answer this question, we evaluate them against 128-iteration GCG. Figure 5 shows that, over the course of adversarial training, all models gain robustness to the stronger adversarial attack. Larger models start with and maintain a robustness advantage over smaller models for proportional amounts of adversarial training, while the rate of improvement is comparable between larger and smaller models.

**For larger models, robustness from adversarial training generalizes to a modified threat model.** An additional concern with the adversarial training setup is that so far we have only studied suffix-based attacks. Could it be that our models are not learning to be *generally* robust, and instead are simply learning to ignore the final 10 tokens? To answer this question, we evaluate against a modified threat model: instead of appending 10 tokens (suffix attack), the adversary now inserts 10 tokens 90% of the way into the prompt (infix attack). Figure 6 shows transfer between adversarially training on the suffix attack and evaluating on the infix attack. Here we observe a divergence between larger and smaller models. While larger models consistently improve in robustness over the course of adversarial training, smaller models appear to slow down their rate of improvement, with some plateauing (smallest Spam model) or even getting worse (smallest IMDB model). This suggests that while adversarial training improves all model sizes, larger models are most likely learning more useful representations to defend against different threat models.

As such, larger models appear to generally be better suited to changes in attack (whether in terms of strength, attack method—see Appendix H—or threat model) than smaller models. However, larger and more capable models are also more desirable targets for an attack. This raises the question: does scaling model size shift the offense-defense balance?

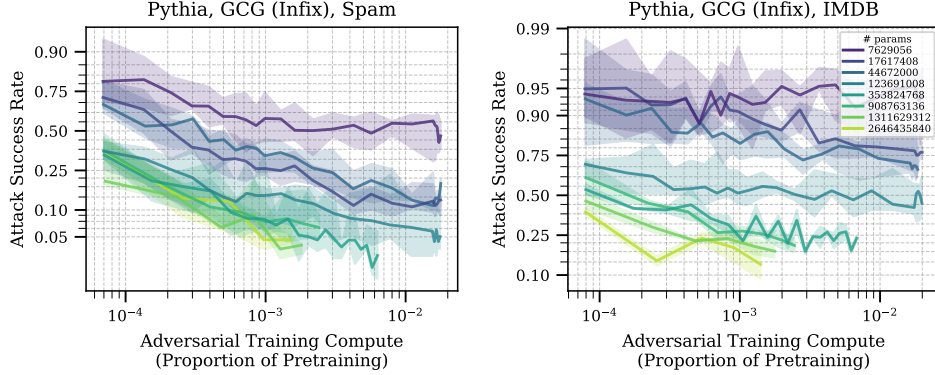

Figure 6: Transfer from adversarial training of Pythia against 64-iteration GCG to a modified 64-iteration GCG attack which places the adversarial text 90% of the way to the end of the prompt, on Spam (**left**) and IMDB (**right**). Larger models improve robustness faster and further than smaller models, with the smallest models plateauing before the end of adversarial training.

## 6 OFFENSE-DEFENSE BALANCE

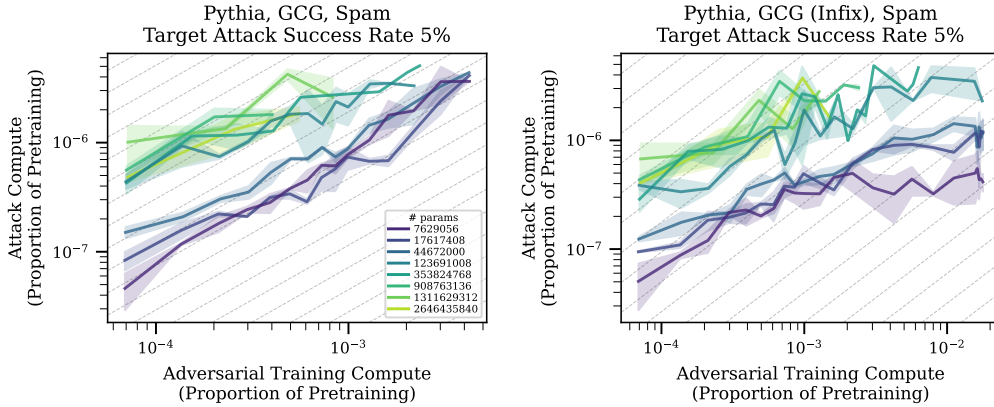

Figure 7: Compute needed to achieve a 5% (interpolated) attack success rate ( $y$ -axis) on a single input using GCG suffix (**left**) and GCG 90% infix (**right**) attacks, vs. adversarial training compute ( $x$ -axis) on GCG suffix attack relative to pretraining compute. Grey dashed lines show  $y = x + b$  for various intercepts  $b$  to show parity lines. Increasing model size helps with transfer, but even at larger scales, attackers have an advantage (slope  $< 1$ ).

In order to compare attack and defense compute directly, we now measure them both *relative* to compute spent during pretraining.<sup>3</sup> Figure 7 corroborates the previous section, showing that larger models generalize better from the *first round* of adversarial training, and so have substantially higher attacker compute costs *even when expressed proportionally to pretraining compute*. That is, attacking larger adversarially trained models with GCG is even more expensive than it would be as a result of the increased model size alone.

On the other hand, the slopes of these graphs show the offense-defense balance tends to favor offense. In particular, with the  $\log_{10}$  axes the slope shows how many factors of 10 more compute an attacker needs to spend to maintain the same success rate against a defender who increases their adversarial training by a factor of 10. If the slope is less (greater) than one, the situation is asymptotically offense (defense) dominant, in that an attacker needs less (more) than 10x their adversarial attack compute in order to maintain the same attack success rate against a defender who 10x'd their adversarial training compute. On the Spam task, we see that at small model sizes on a suffix-based attack, attacker and defender appear to be at compute parity (slope  $\approx 1$ ). However, at larger model

<sup>3</sup>See Appendix G for details on how attack compute was estimated.

sizes, and in the case of transfer to a 90% infix attack, attacker has the advantage (slope  $< 1$ ). The offense-defense balance is similarly skewed towards offense in the IMDB setting (Appendix D.5).

## 7 LIMITATIONS AND FUTURE WORK

In this work, we focus on evaluating the robustness of classifiers, which enabled us to study scaling across three orders of magnitude with a clear notion of attack success. Classifiers such as moderation filters are often used in security-critical settings, making their robustness of immediate practical relevance. Furthermore, since generation is a harder task, we expect robustness of classifiers to serve as a lower bound to robustness of generative models. However, studying jailbreaks on open-ended tasks requires generative models. While our initial results on generative models show similar behavior to those on classifiers, it would be valuable to study a wider class of generative models.

Additionally, most of our experiments used the same attack method both to find examples to use for adversarial training (defense) and to evaluate robustness (attack). However, in the real world, this is an unrealistic threat model for both attacker and defender. On the attack side, if an attacker has access to the weights of a model, there is no need for adversarial attack—a small amount of finetuning is a more effective use of compute to bypass safety training (Pelrine et al., 2023). If the attacker does not have model access, then the attacker must use a black-box attack like BEAST instead of a gradient-based attack like GCG. On the defense side, the defender can afford to do more than adversarially train with GCG. For example, they can use a more compute-efficient attack method, like Latent Adversarial Training (Casper et al., 2024), to find examples on which to adversarially train. Furthermore, they can employ other defenses on top of adversarial training. With this in mind, we believe it would be of value to determine whether the offense-defense balance remains in the attacker’s favor under a more realistic threat model.

Similarly, our analysis focused on asymptotic aspects and quantifiable trends. This is relevant for understanding relative changes to the status quo, but is insufficient to comment on the absolute costs related to attacks. Increasing the computational cost of an attack by 2 orders of magnitude has very different implications for the practicality of an attack that currently costs \$0.01 versus one that costs \$10,000. An important direction for future work is to quantify the absolute costs of current attacks and defense, combining this with our scaling trends to forecast the cost of attacking and defending future models. This would enable defenders to determine the cost of defending against different categories of attacker—and at what point, if at all, attack cost exceeds the cost of the attacker training a model without safeguards.

## 8 CONCLUSION

We find that scaling attack and defense compute significantly and predictably improve attack and defense performance. Adversarial training is orders of magnitude more compute efficient as a defense than scaling base model size, and larger models generalize better from adversarial training. This suggests substantially more robust models could be trained by diverting a small fraction of pretraining compute towards adversarial training, with *increasing* benefits for larger models.

Given both attack and defense benefit from scale, which has the upper hand? Currently offense is winning: an attacker consistently needs to less than double their attack compute in order to maintain the same success rate against a defender who doubled their adversarial training compute. However, the offense advantage is slight: even a modest and well-targeted algorithmic improvement could shift the balance towards defense. We propose that actualizing this shift should be the key design goal for new defense methods. Crucially, this will require a shift from today’s common practice of evaluating defenses by a single point on the model size and defense compute frontier, to evaluating defenses by their scaling trends.

## A DATASETS

Table 3 displays representative examples from the six datasets described in Section 3, with our attacks (Section B) applied to some of the examples.

Since the context window for the Pythia model family is 2048 tokens, we must be careful not to run models on datapoints that are longer than this threshold. For each dataset, we filter out the few datapoints that are empty (i.e., a few train datapoints in Spam) or exceed 1000 tokens. We cap at 1000 tokens instead of the 2048-token Pythia context length (Biderman et al., 2023) because we wanted to leave open the possibility of using models with a 1024-token context length like GPT-2, and we additionally left 24 extra tokens as buffer for purposes such as adversarial attacks and special tokens. Table 2 shows the number of datapoints in each dataset, as well as the number of datapoints filtered out for length. We generally do not train on the whole dataset, however—our training runs sample 20,000 datapoints from the train set.

Table 2: The initial sizes of each dataset as well as the number of datapoints filtered for being too long or empty. We train on a subset of 20,000 datapoints sampled with a fixed seed.

Dataset	Train	# filtered	Validation	# filtered
Spam	31,716	2426	2,000	148
IMDB	25,000	635	25,000	599

919	IMDB	GCG	You will be given a review below to classify	NEGATIVE
920			based on its sentiment. The review will be either	(0)
921			positive or negative. If the review is positive,	
922			return POSITIVE. If the review is negative, return	
923			NEGATIVE.	
924			I expected a lot more out of this film. The	
925			preview looked interesting so I decided to check	
926			it out. Bottom line is that "The Adventures	
927			of Sebastian Cole" only had one decent thing:	
928			Adrian Grenier.  I really like	
929			Grenier and found his performance to be very	
930			pleasing. The character is designed well, but	
931			everything else sort of just drifts along through	
932			the duration of the movie. Clark Gregg is really	
933			good, but I don't think that his character was	
934			explained too well. I mean there's not too much	
935			to explain; he wants to become a woman. Still,	
936			something was missing.   The	
937			obvious low budget of the film was nice to see.	
938			I enjoyed that the movie was filmed on just a	
939			script (a bad one at that) and just a few actors.	
940			It was a nice change.  While	
941			the main idea of the film was actually okay,	
942			it became disappointing to see a lot of scenes	
943			that had nothing to do with it just thrown in	
944			here and there. Like I said, the script looked	
945			promising and I must say that I was interested	
946			where director Tod Williams was headed, but it	
947			was basically a very slow movie with not too	
948			good of dialogue.  "Sebastian"	
949			started to look good towards the end, but again, it	
950			fell right back down into a hole. The acting was	
951			mostly good, the writing is in need of some work,	
952			yet the budget of the film helped it out in the long	
953			run.  I would recommend this to	
954			someone if they wanted to watch a quiet movie	
955			with a strong lead character, but other than that I	
956			would stay away. Personally, I wouldn't watch it	
957			twice. <b>gaveits Always 7 proportion ("[Customer</b>	
958			<b>fruit Service requires</b>

977			NEGATIVE.	
978			This is one of my favorite T.V shows of all	
979			time, Rowan Atkinson is simply a genius!, and it's	
980			only fitting that i chose this to be my 1000 review!.	
981			I can't begin to tell you how much i love Mr.	
982			Bean he's the man, and what amazes me, is how	
983			he gets out of these incredibly difficult situations,	
984			and he is always so creative,plus Robyn Driscoll	
985			also deserves accolades!, he is also a genius!.	
986			My favorite bit that he has done is the Amazing	
987			Adventures of Mr. Bean and while all the rest of	
988			them are amazing, this remains my true favorite,	
989			plus i wish the show didn't stop so soon!. Each	
990			episode is brilliantly written, and they were all	
991			masterfully directed, plus Each episode is a classic	
992			in my eyes!. This show is incredibly popular,	
993			and i can definitely see why, as it's quite possibly	
994			the funniest show ever. The character actors all	
995			played there roles really well, especially Robyn	
996			Driscoll and Matilda Ziegler (as Irma). This is	
997			one of my favorite T.V shows of all time Rowan	
998			Atkinso is simply put a genius and an incredibly	
999			talented comedian (possibly the best!), and it's	
1000			only fitting that i chose this to be my 1000 review f	
1001			you haven't seen this show , drop what your doing	
1002			right now and go check it out, you will not regret	
1003			it trust me it's one <b>badly\\ \\ \\ Built production</b>	
1004			<b>masterpiece /* 1500 NuclotechnologyWHAT</b> of	
1005			the best T.V shows ever!,and i will continue to	
1006			watch the show over and over again, i never tire of	
1007			it!, Mr. Bean Rules!. ***** out of 5

## B ADVERSARIAL ATTACKS

The primary attack we use is GCG from Zou et al. (2023). We use the simple, single-prompt version described in Algorithm 1 of Zou et al. (2023) with the modifiable subset  $\mathcal{I}$  set to be the final  $N$  tokens of the text before the `Answer:` prompt. We use a suffix of length  $N = 10$ , batch size  $B = 128$ , and  $k = 256$  top substitutions for all experiments. In Section 5.1 we also use GCG with a slightly different threat model, inserting  $N$  tokens 90% of the way into the part of the prompt that varies among examples in each dataset. For example, in the Spam dataset, the varying part of the prompt is everything after “HAM.” but before “Answer:”.

We describe the baseline RandomToken algorithm in Algorithm 2. RandomToken is designed to be similar to GCG except that RandomToken does not use gradient-guided search. Instead, for each iteration we replace each token in the adversarial suffix with a new token chosen uniformly at random from the vocabulary of the model. We then evaluate the new prompt to see if it has caused the model to give an incorrect answer and stop the attack if it has. If no iteration was successful, we return the adversarial suffix from the final iteration. An iteration of RandomToken is much cheaper than an iteration of GCG, so we use much higher iteration counts for RandomToken than GCG.

---

### Algorithm 2 RandomToken Attack

---

**Input:** Initial prompt  $x_{1:n}$ , modifiable subset  $\mathcal{I}$ , iterations  $T$ , success criterion  $S$ , vocabulary  $V$   
**for**  $t = 1$  **to**  $T$  **do**  
  **for**  $i \in \mathcal{I}$  **do**  
     $x_i \leftarrow \text{Uniform}(V)$   
  **end for**  
  **if**  $S(x_{1:n})$  **then**  
    **return:**  $x_{1:n}$   
  **end if**  
**end for**  
**return:**  $x_{1:n}$   
**Output:** Optimized prompt  $x_{1:n}$

---

BEAST is described in Sadasivan et al. (2024). To make it work against classification-based victims, we sample from a separate base model (pythia-14m for Pythia-based victims and Qwen2.5-0.7B for Qwen-based victims) instead of from the victim. The original reasons for sampling from the victim is to keep the perplexity low to circumvent perplexity-filter-based defenses and to maintain readability, neither of which are important for our experiments. We choose the number of tokens (equivalently, the number of iterations) to be 25 and the beam size  $k$  to be 7. These parameter settings are lower than those used by Sadasivan et al. (2024) for jailbreaks, giving a weaker but faster attack.

## C SCALING TRENDS IN ATTACKS ON FINETUNED CLASSIFIERS

### C.1 PERFORMANCE ON CLEAN DATA

In Figure 8 we show the performance of the finetuned models on clean data, before any adversarial attack.

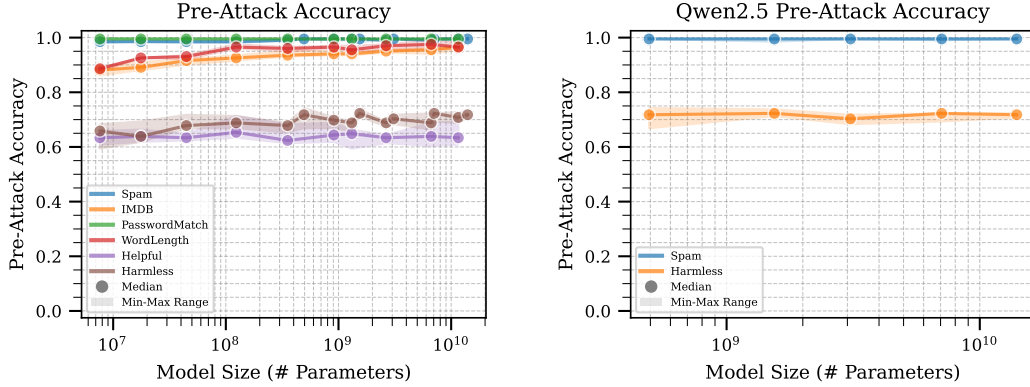

Figure 8: Performance across model sizes and tasks before any attacks. All models achieve  $>85\%$  on all tasks except Helpful and Harmless, which are significantly harder—no model achieves 75% on them.

In Figure 9 we show the pre-attack accuracy and post-attack accuracies of the Qwen2.5 model family on the StrongREJECT task.

Figure 9: Performance across model sizes before attack (left) and after a GCG adversarial attack (right). Larger models perform better both before and after the attack.

### C.2 ATTACK STRENGTHS

Table 4 shows the attack strengths used in Figure 2. The shaded regions are difficult to read precisely in Figure 2, so in Figure 11 we reproduce Figure 2 but with each task given its own plot.

Table 4: Attack strengths used against finetuned models across both attacks and all tasks.

Model	Task	# Attack Iterations
GCG	IMDB	10
GCG	Spam	10
GCG	PasswordMatch	10
GCG	WordLength	2
GCG	Helpful	2
GCG	Harmless	2
RandomToken	IMDB	1280
RandomToken	Spam	1280
RandomToken	PasswordMatch	1280
RandomToken	WordLength	1280
RandomToken	Helpful	1280
RandomToken	Harmless	1280

## C.3 ATTACK SUCCESS RATE WITH RANDOMTOKEN ATTACK

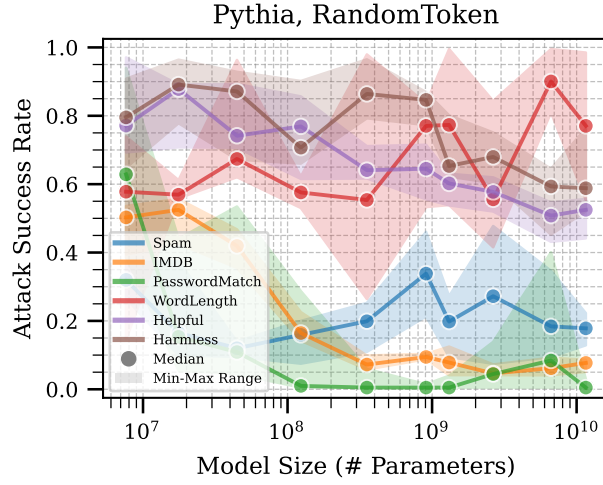

Figure 10: Attack success rate ( $y$ -axis) of RandomToken against different models sizes ( $\log_{10}$  scale  $x$ -axis) of Pythia on six classification tasks. We plot the median over 5 random seeds and shade the region between the min and max. We use a RandomToken attack strength of 1280 iterations for all tasks. We observe a noisy and task-dependent trend of larger models generally, but not always, achieving better robustness against the attack. See Figure 11 to see each task on its own plot for readability.

## C.4 INDIVIDUAL GCG AND RANDOMTOKEN ATTACKS

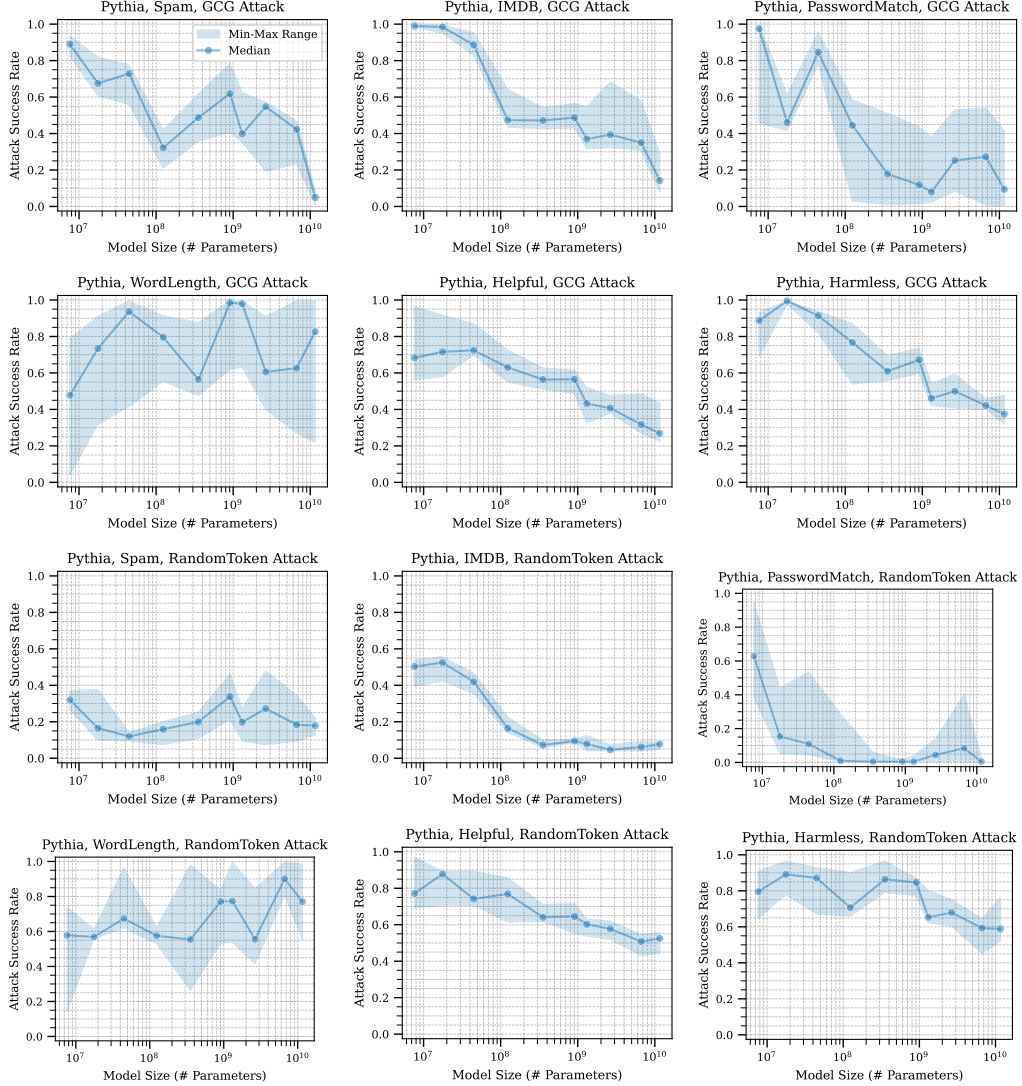

Figure 11: Attack success rate ( $y$ -axis) of GCG and RandomToken attacks against Pythia models of varying sizes (log<sub>10</sub>-scale  $x$ -axis) finetuned on all tasks. The plotted data is the the same as in Figure 2, but each task is given its own plot for readability.

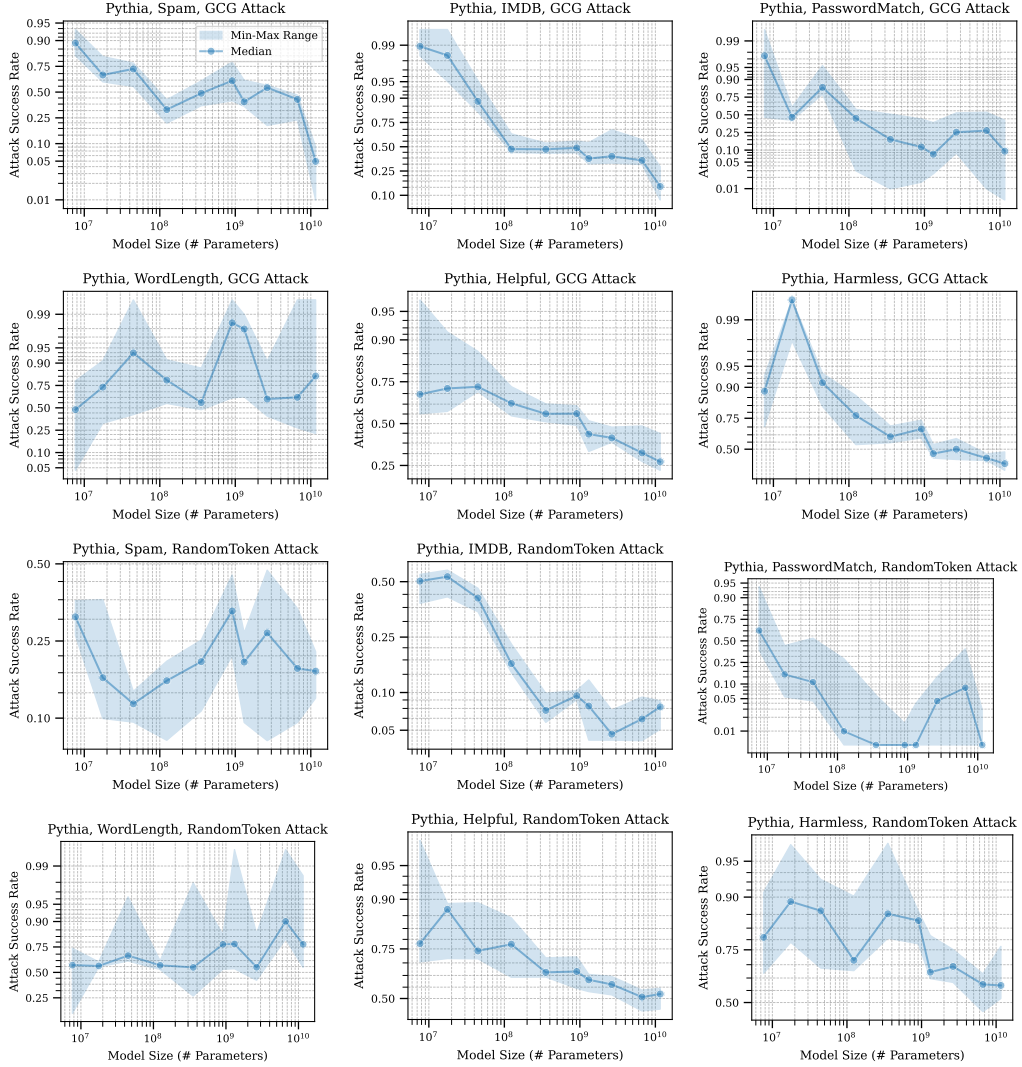

Figure 12: Attack success rate (logit<sub>10</sub>-scale  $y$ -axis) of GCG and RandomToken attacks against Pythia models of varying sizes (log<sub>10</sub>-scale  $x$ -axis) finetuned on all tasks. The plotted data is the same as in Figure 11, but with a logit-scale  $y$ -axis.

## C.5 ATTACK SUCCESS RATE LOGIT VS. ATTACK COMPUTE

### C.5.1

Denote attack success probability as  $\rho$ , and denote compute as  $\kappa$ . Let  $y = \log_{10} \left( \frac{\rho}{1-\rho} \right)$  and  $x = \log_{10}(\kappa)$ . Suppose there is a linear relationship  $y = ax + b$ . Then:

$$\log_{10} \left( \frac{\rho}{1-\rho} \right) = a \log_{10}(\kappa) + b \quad (1)$$

Define  $\sigma_{10}(x) = \frac{10^x}{1 + 10^x}$ . Observe that

$$\begin{aligned} \sigma_{10} \left( \log_{10} \left( \frac{\rho}{1-\rho} \right) \right) &= \frac{\rho/(1-\rho)}{1 + \rho/(1-\rho)} \\ &= \frac{\rho}{1-\rho + \rho} \\ &= \rho. \end{aligned}$$

Now, applying  $\sigma_{10}$  to both sides of eq. 1 gives:

$$\begin{aligned} \rho &= \sigma_{10}(a \log_{10}(\kappa) + b) \\ &= \frac{10^{(a \log_{10}(\kappa) + b)}}{1 + 10^{(a \log_{10}(\kappa) + b)}} \\ &= \frac{10^b \kappa^a}{1 + 10^b \kappa^a} \end{aligned}$$

For small values of  $10^b \kappa^a$ ,  $\rho \approx 10^b \kappa^a$ , and so  $a$  describes a power law for how attack success rate initially scales with compute when the success rate is very small.

For large values of  $10^b \kappa^a$ ,

$$\begin{aligned} \rho &= \frac{10^b \kappa^a}{1 + 10^b \kappa^a} \\ 1 - \rho &= \frac{1 + 10^b \kappa^a - 10^b \kappa^a}{1 + 10^b \kappa^a} \\ 1 - \rho &= \frac{1}{1 + 10^b \kappa^a} \\ 1 - \rho &\approx 10^{-b} \kappa^{-a}, \end{aligned}$$

so  $-a$  defines a power law for how attack failure rate  $1 - \rho$  scales with compute when the failure rate is very small.

### C.5.2 GCG ATTACKS

Figures 13, 14 and 15 provide the slopes of the  $\log_{10}$  attack success rate using GCG. See C.5.3 for the analogous figures for RandomToken.

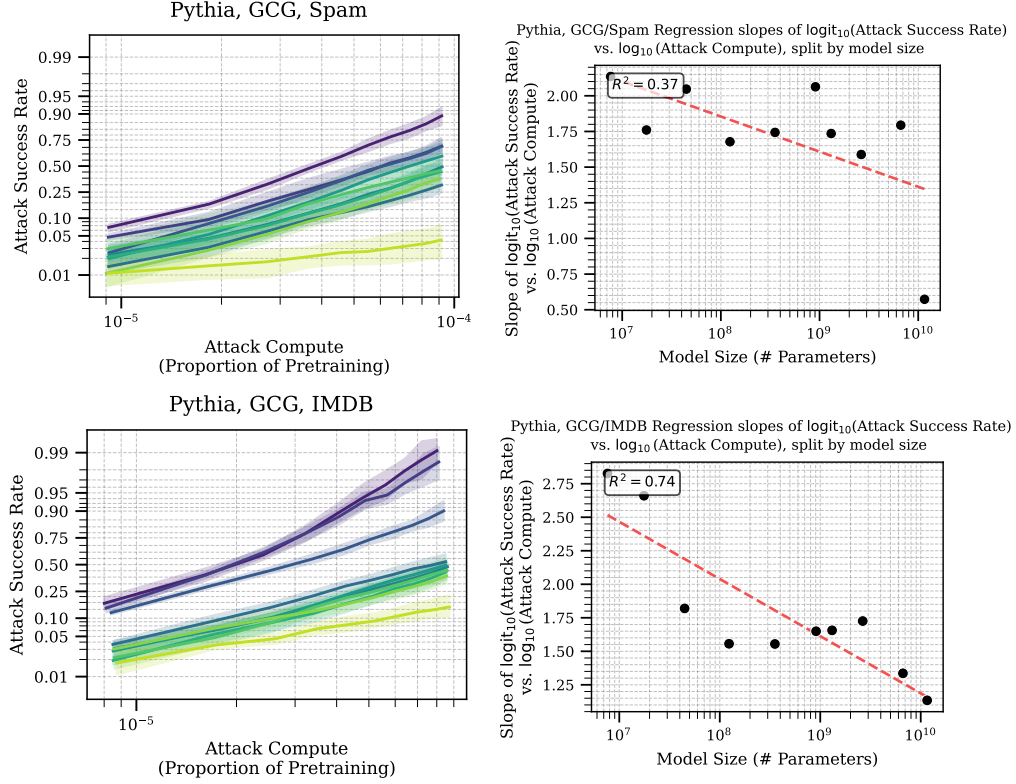

Figure 13: Attack effectiveness scaling for GCG on IMDB and Spam.

Left: Attack success rate ( $\log_{10}$  scale  $y$  axis) vs. Attack Compute ( $\log_{10}$  scale  $x$  axis)  
 Right: Slopes of  $\log_{10}$  attack success rate using GCG over  $\log_{10}$  attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size ( $\log_{10}$   $x$ -axis). We find that models generally become less marginally attackable on these datasets with increasing size.

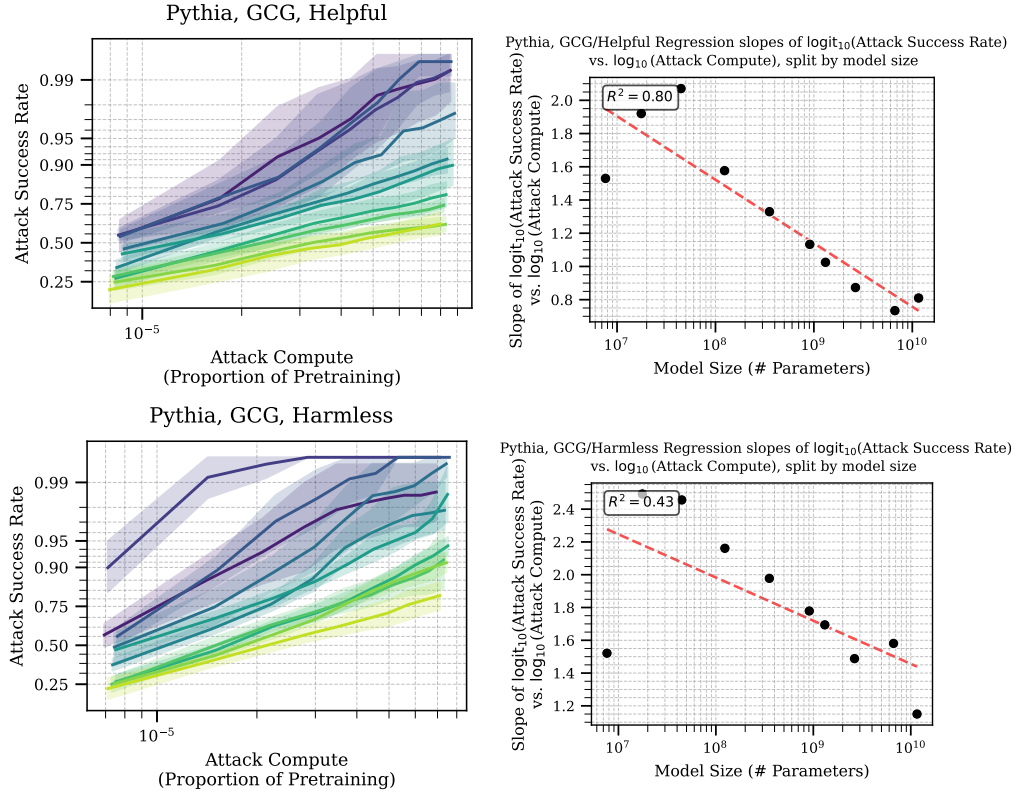

Figure 14: Attack effectiveness scaling for GCG on Helpful, and Harmless.  
 Left: Attack success rate (logit<sub>10</sub> scale  $y$  axis) vs. Attack Compute (log<sub>10</sub> scale  $x$  axis)  
 Right: Slopes of logit<sub>10</sub> attack success rate using GCG over log<sub>10</sub> attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size (log<sub>10</sub>  $x$ -axis). We find that models generally become less marginally attackable on these datasets with increasing size.

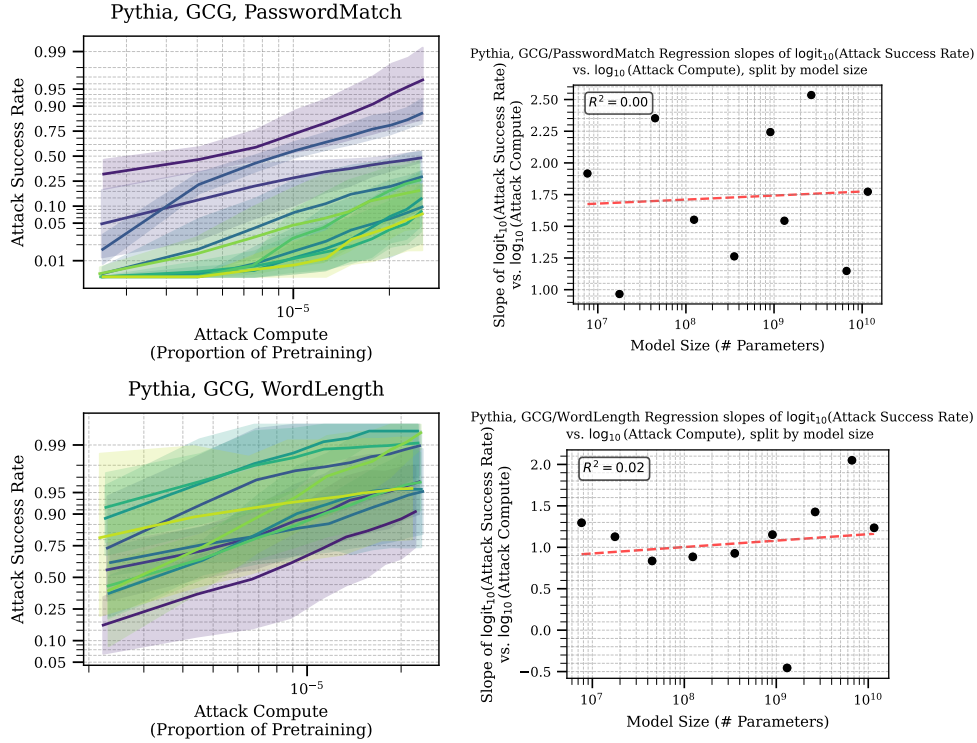

Figure 15: Attack effectiveness scaling for GCG on Password Match and Word Length. Left: Attack success rate ( $\log_{10}$  scale  $y$  axis) vs. Attack Compute ( $\log_{10}$  scale  $x$  axis) Right: Slopes of  $\log_{10}$  attack success rate using GCG over  $\log_{10}$  attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size ( $\log_{10}$   $x$ -axis). We find that model size is more-or-less irrelevant for marginal attackability on these tasks.

### C.5.3 RANDOM TOKEN ATTACKS

Figures 16, 17 and 18 provide the slopes of the  $\log_{10}$  attack success rate using RandomToken.

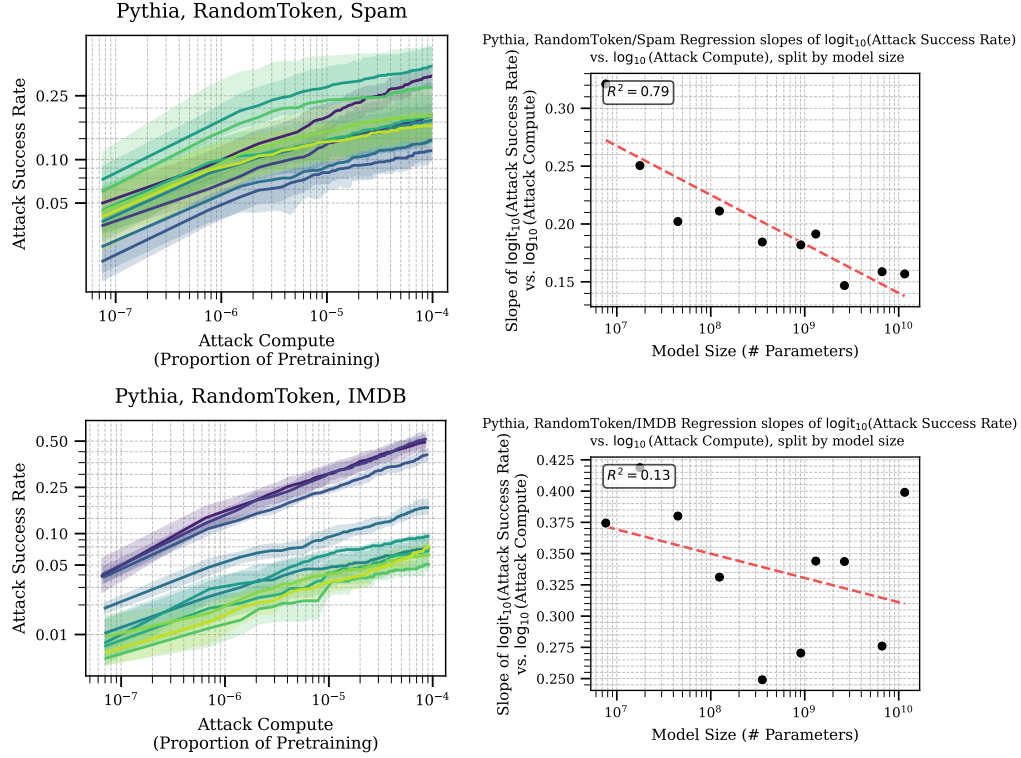

Figure 16: Attack effectiveness scaling for RandomToken on Spam and IMDB.  
 Left: Attack success rate ( $\log_{10}$  scale  $y$  axis) vs. Attack Compute ( $\log_{10}$  scale  $x$  axis)  
 Right: Slopes of  $\log_{10}$  attack success rate using GCG over  $\log_{10}$  attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size ( $\log_{10}$   $x$ -axis).  
 We find that models generally become less marginally attackable on these datasets with increasing size.

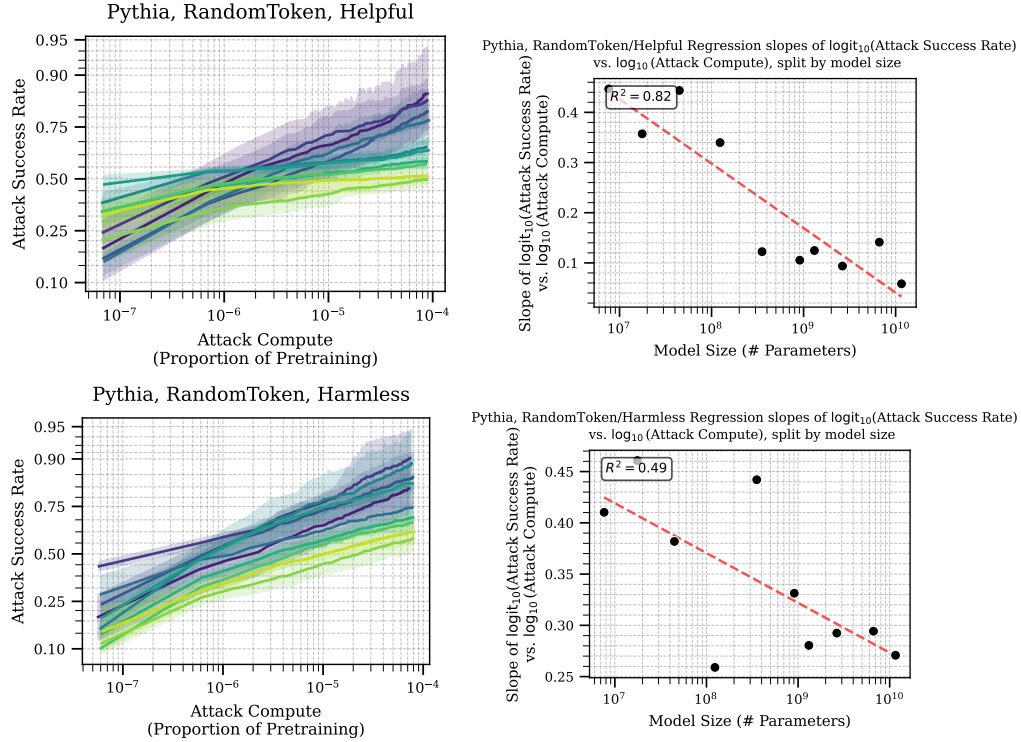

Figure 17: Attack effectiveness scaling for RandomToken on Helpful and Harmless. Left: Attack success rate (logit<sub>10</sub> scale y axis) vs. Attack Compute (log<sub>10</sub> scale x axis) Right: Slopes of logit<sub>10</sub> attack success rate using GCG over log<sub>10</sub> attacker compute as a fraction of pretraining compute (y-axis) vs. Pythia model size (log<sub>10</sub> x-axis). We find that models generally become less marginally attackable on these datasets with increasing size.

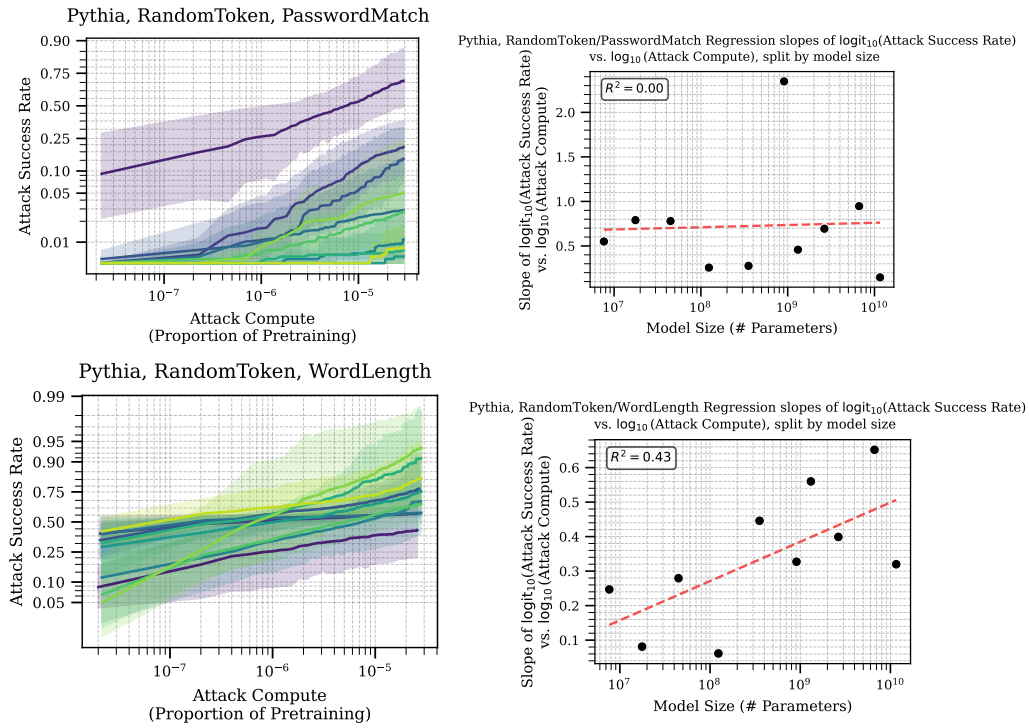

Figure 18: Attack effectiveness scaling for RandomToken on PasswordMatch and WordLength  
Left: Attack success rate ( $\log_{10}$  scale  $y$  axis) vs. Attack Compute ( $\log_{10}$  scale  $x$  axis)  
Right: Slopes of  $\log_{10}$  attack success rate using GCG over  $\log_{10}$  attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size ( $\log_{10}$   $x$ -axis).  
We find that model size typically decreases marginal attackability on PasswordMatch but *increases* it on WordLength.

## D ADVERSARIAL TRAINING

### D.1 PERFORMANCE ON CLEAN DATA

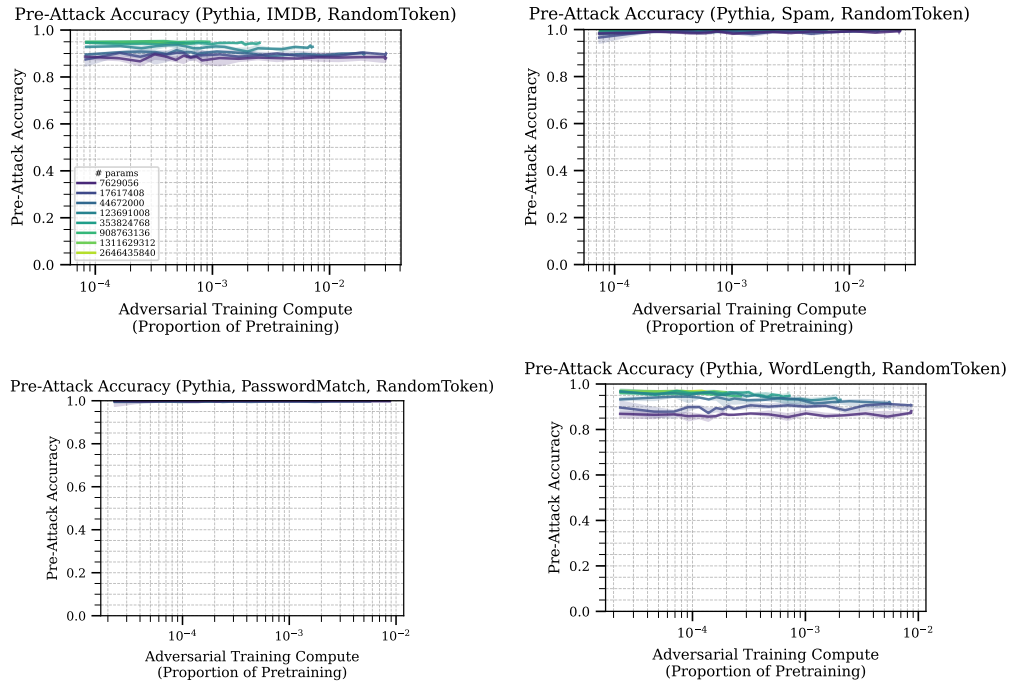

Figure 19: Accuracy on clean data over the course of adversarial training using the RandomToken attack. All models begin with and maintain above 80% on all tasks.

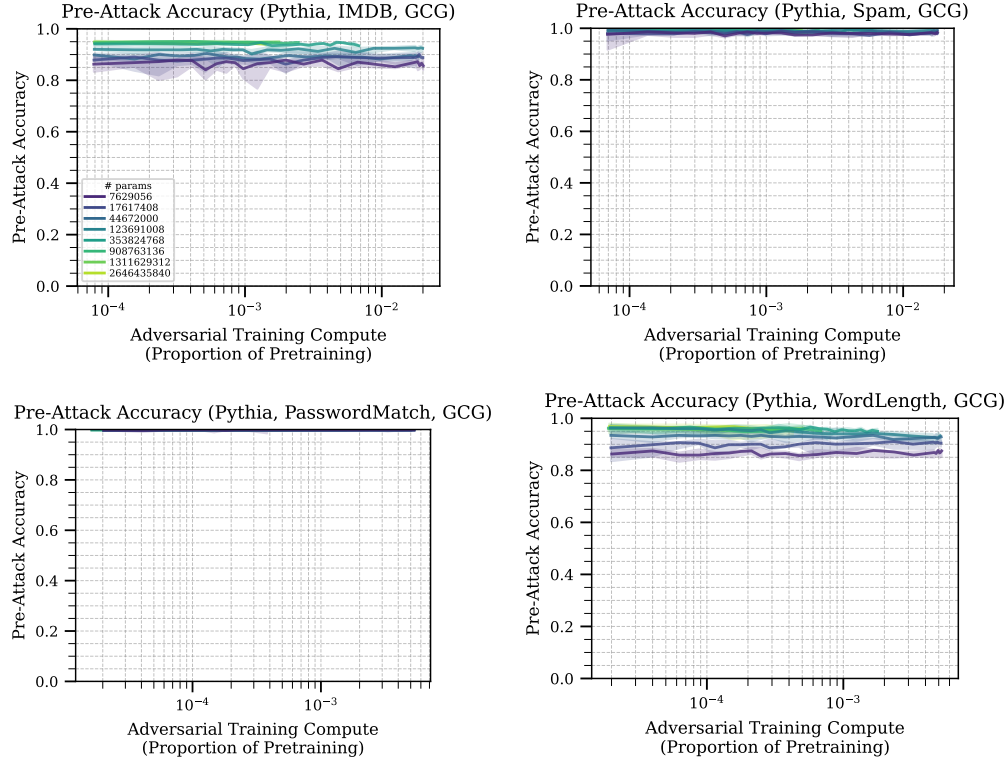

Figure 20: Accuracy on clean data over the course of adversarial training using the GCG attack. All models begin with and maintain above 80% on all tasks.

## D.2 ADVERSARIAL TRAINING SETUP

The adversarial training procedure described in Section 5 and visualized in Figure 21 starts with an empty pool of attacked examples. Then the algorithm iteratively performs the following steps:

- Adversarially attack a subset of the original training dataset.
- Add those attacked examples to the pool of attacked examples.
- Train the model on a small dataset of clean and attacked datapoints, drawing from the original training set and the pool of attacked examples.
- Save model checkpoint for future evaluation.

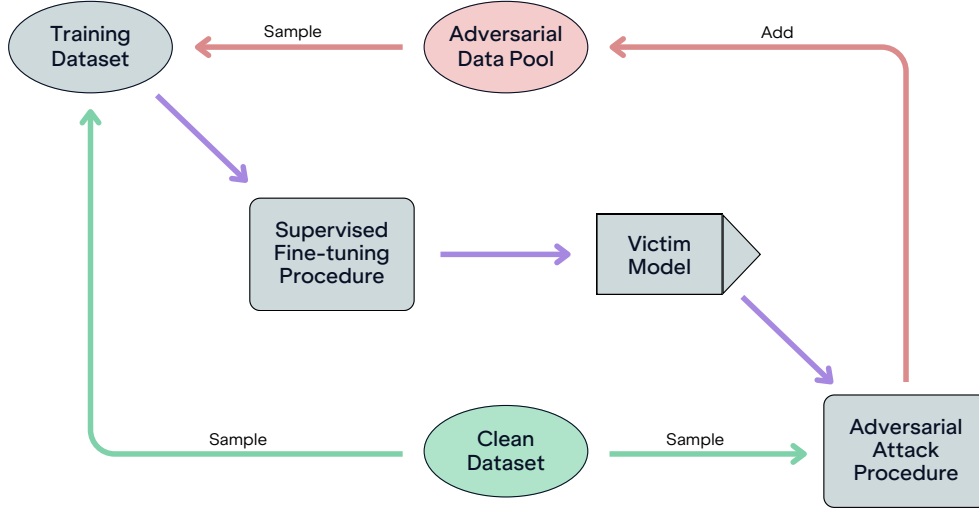

Figure 21: Our adversarial training setup.

We begin with the finetuned model trained as in Section 4. In order for each round of adversarial training to use the same amount of compute for a given model size, we use a constant dataset size of 1,000 examples for each round of adversarial training. Since we are constantly finding new attacked examples, we need a way to decide which ones to train on each round. In our experiments, we sample from a fixed set of  $n_{\text{clean}} = 20,000$  clean examples (the original training dataset) and a growing set of  $n_{\text{adv}} = 200 \cdot r$  adversarial examples where  $r$  is the round number. From these combined clean and attacked datasets, we sample  $n_{\text{aug}} = 1000$  datapoints on which to train each round. We sample  $s_{\text{adv}} = \min(80\% \times 1000, n_{\text{adv}})$  from the adversarial dataset, and the remaining  $s_{\text{clean}} = n_{\text{aug}} - s_{\text{adv}}$  from the clean data.

We sample uniformly from the clean data whereas from the adversarial dataset we use exponential sampling to upweight both recent and successful examples. Before round 4, we take the whole adversarial dataset since we have fewer than 800 examples to choose from. After round 4, we rank all of the datapoints by loss ( $r_i^{\text{loss}} : 0 < i < n_{\text{adv}}$ ) and by recency ( $r_i^{\text{time}} : 0 < i < n_{\text{adv}}$ ), then take the simple mean of these two to aggregate to a single ranking  $r_i = \frac{1}{2} (r_i^{\text{loss}} + r_i^{\text{time}})$ . We sample adversarial examples with exponential weights  $\exp\{\lambda \cdot r_i\}$  where  $\lambda = 0.005$  corresponds to a half-life of  $\frac{\ln(2)}{0.005} \approx 140$  examples.

As adversarial training continues, generating successful attacks becomes more difficult. In order to compensate for this, we employ a linear schedule in order to ramp up the attack strength across rounds of adversarial training.<sup>4</sup> In round  $r$  of a total  $R$  rounds, the number of iterations  $k$  used for the attack is given by  $k = k_{\text{start}} + \frac{r}{R}(k_{\text{end}} - k_{\text{start}})$ . For GCG, we use  $k_{\text{start}} = 8, k_{\text{finish}} = 64$ . For RandomToken, we use  $k_{\text{start}} = 1024, k_{\text{finish}} = 2048$ . In order to spend similar amounts of compute at each model size, we set  $R = 8$  for 1B models, then scale up/down proportionally for smaller/larger models, clipped between 5 and 60 (250 when using the RandomToken attack) so that the 12B models run for 5 rounds while the 14M models run for 60 (250 for RandomToken) rounds.

We evaluate the models using a dataset size of 500 for both clean and attacked validation datasets.

<sup>4</sup>With a fixed attack strength, the model in later rounds of adversarial training is extremely robust to attacks of that fixed strength and the adversarial attack struggles to succeed at all.

### D.3 ADVERSARIAL ROBUSTNESS DURING ADVERSARIAL TRAINING

We evaluate the adversarial robustness of our models with a relatively weak 12-iteration GCG attack during the initial phases of adversarial training. We plot this improvement in robustness in Figure 22, while we show performance against a stronger 128-iteration GCG attack in Figures 23 and 24.

Figure 22: Attack success rate ( $y$ -axis) of 12-iteration GCG against Pythia models of varying sizes ( $\log_{10}$  scale  $x$ -axis) finetuned on Spam (left) and IMDB (right). We plot the median over 3 random seeds and shade the region between min and max. Adversarial training quickly leads to improved model robustness across model sizes. Note that we adversarially trained the larger models only for 5 rounds, so the “Round 10” curve ends early.

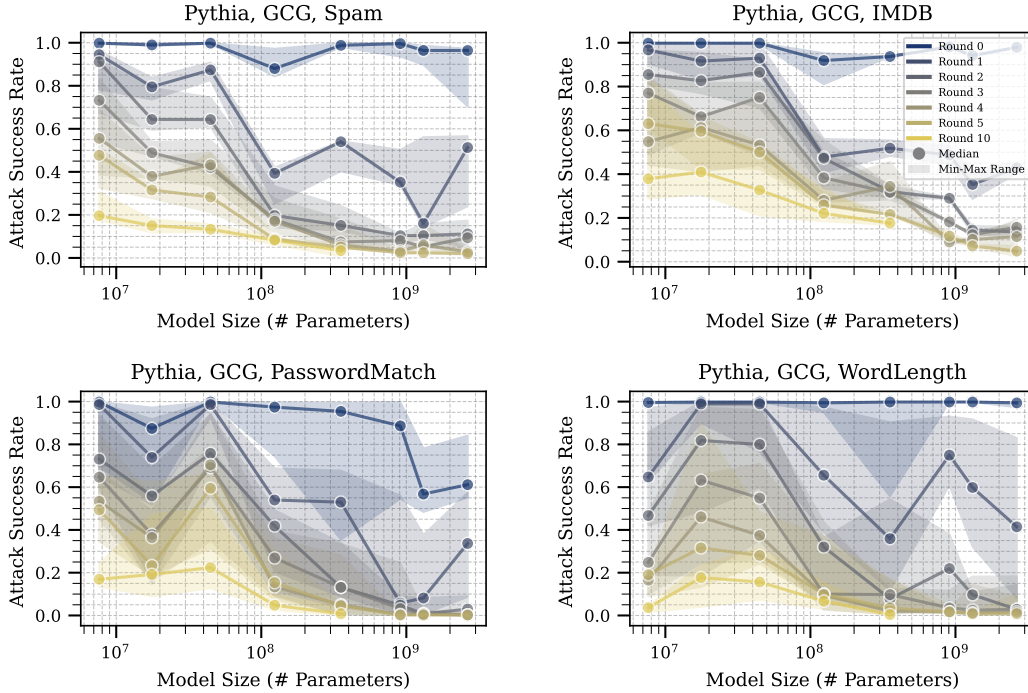

Figure 23: Attack Success Rate ( $y$ -axis) as a function of model size ( $x$ -axis) over the first few rounds of adversarial training (color), evaluated with a 128-iteration GCG attack.

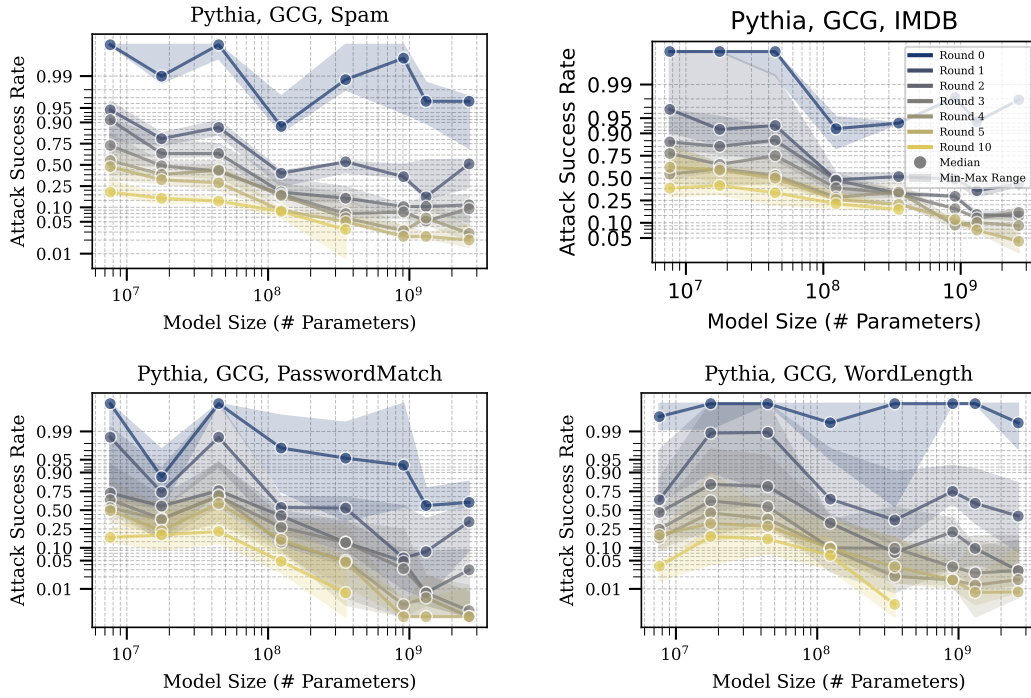

Figure 24: Attack Success Rate (logit<sub>10</sub>  $y$ -axis) as a function of model size ( $x$ -axis) over the first few rounds of adversarial training (color), evaluated with a 128-iteration GCG attack.

## D.4 FIGURE 4 EXTENSIONS

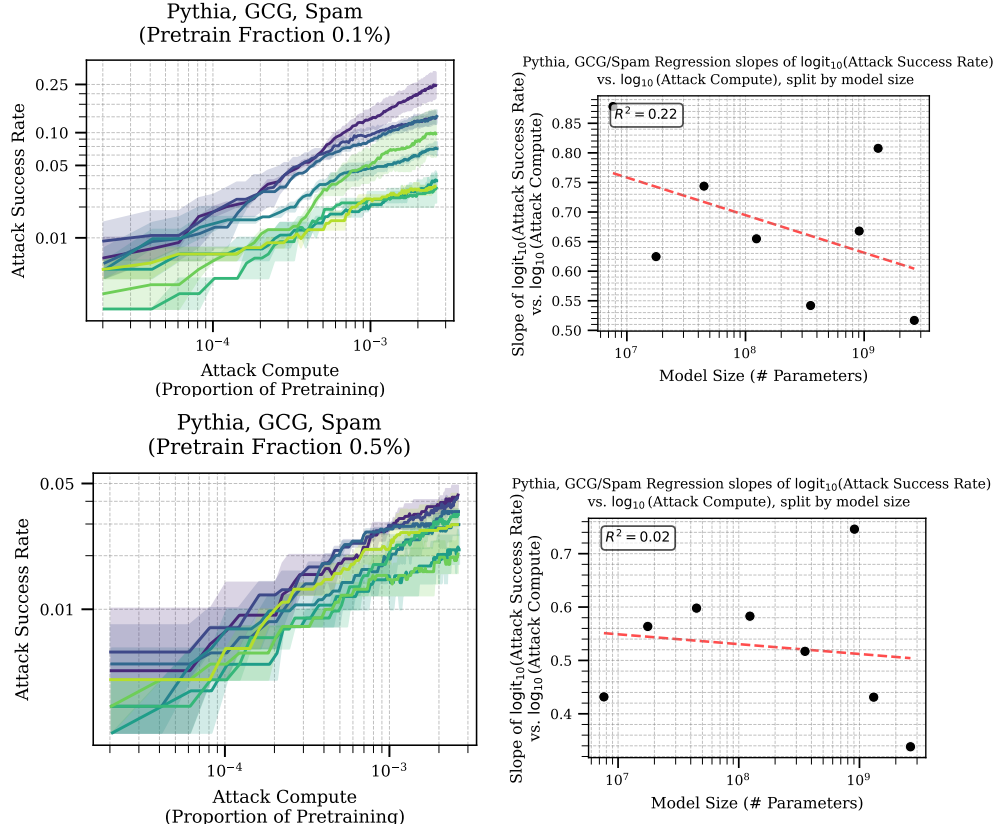

Figure 25: Impact of Adversarial Training using GCG on attackability using 128-iteration GCG of adversarial training after using 0.1% of pretraining compute (top) and after using 0.5% of pretraining compute (bottom)

Left: Attack success rate ( $\log_{10}$ -scale  $y$ -axis) of up to 128 iterations ( $x$ -axis) of GCG against Pythia models of varying sizes (line color)

Right: Slopes of  $\log_{10}$  attack success rate using GCG over  $\log_{10}$  attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size ( $\log_{10}$   $x$ -axis).

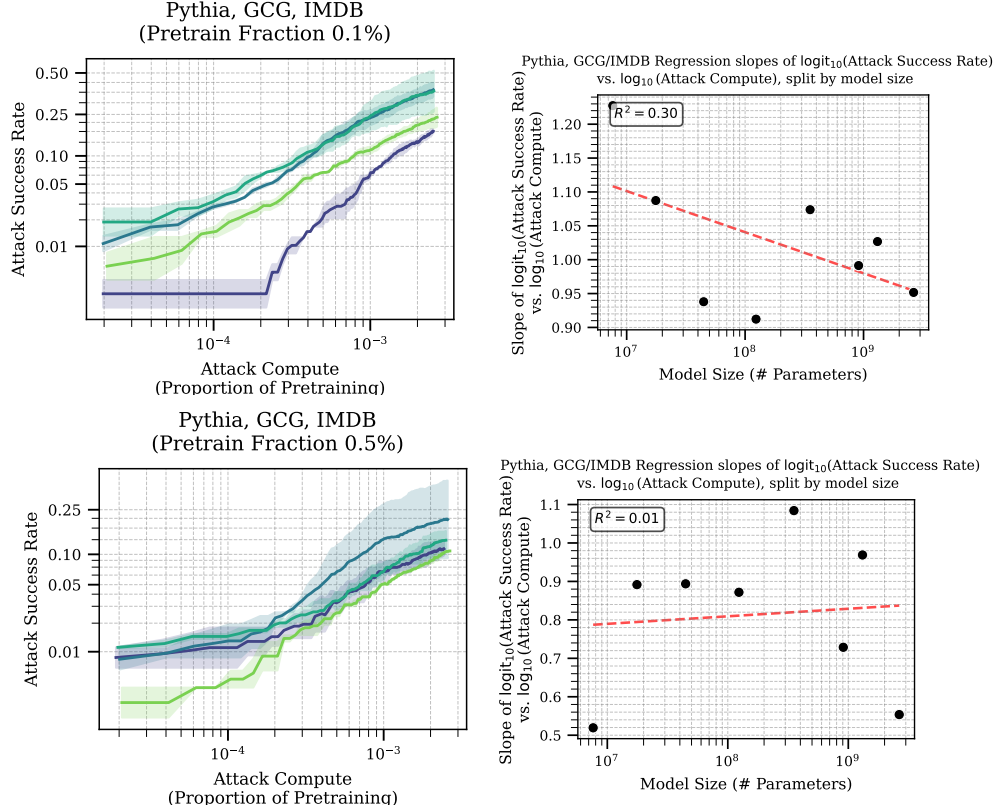

Figure 26: Impact of Adversarial Training using GCG on attackability using 128-iteration GCG of adversarial training after using 0.1% of pretraining compute (top) and after using 0.5% of pretraining compute (bottom)

Left: Attack success rate (logit<sub>10</sub>-scale  $y$ -axis) of up to 128 iterations ( $x$ -axis) of GCG against Pythia models of varying sizes (line color)

Right: Slopes of logit<sub>10</sub> attack success rate using GCG over log<sub>10</sub> attacker compute as a fraction of pretraining compute ( $y$ -axis) vs. Pythia model size (log<sub>10</sub>  $x$ -axis).

## D.5 OFFENSE-DEFENSE BALANCE

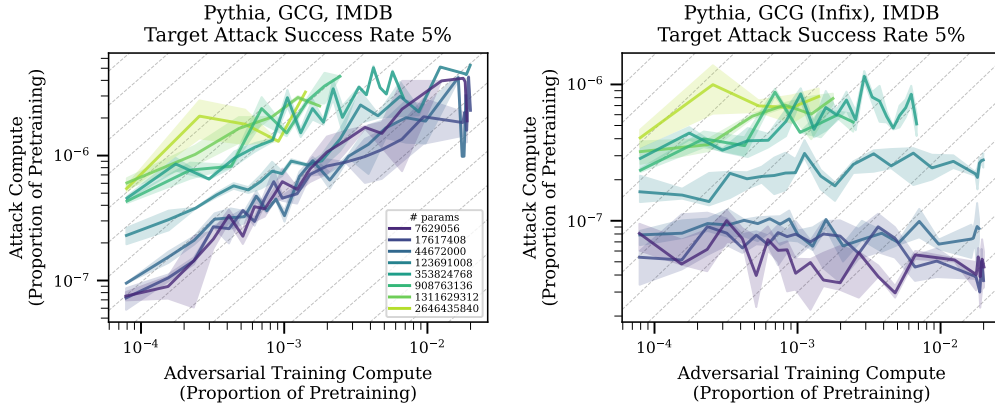

Figure 27: Compute needed to achieve a 5% (interpolated) attack success rate ( $y$ -axis) on a single input using GCG suffix (**left**) and GCG 90% infix (**right**) attacks, vs. adversarial training compute ( $x$ -axis) on GCG suffix attack relative to pretraining compute. Grey dashed lines show  $y = x + b$  for various intercepts  $b$  to show parity lines. Increasing model size helps with transfer, but even at larger scales, attackers have an advantage (slope  $< 1$ ).

## E ESTIMATED COMPUTE CALCULATIONS

To estimate compute costs, we use approximations from Kaplan et al. (2020). To estimate training compute, we use the

$$C_{train} \approx 6ND$$

approximation (where  $C_{train}$  is total training FLOPs,  $N$  is the number of parameters in the model, and  $D$  is the number of tokens in the dataset). To estimate the forward and backward pass costs, we use  $C_{forward} \approx 2ND$  and  $C_{backward} \approx 4ND$  respectively.

### E.1 PRETRAINING COMPUTE CALCULATION

In many of our figures, we represent compute as a fraction of the pretraining cost. We do this to allow an apples-to-apples comparison of attacks of a fixed number of iterations across model sizes. Using GCG or RandomToken for a fixed number of iterations to attack a larger model takes more compute than to attack a smaller model. This is because the cost of each iteration is proportional to the cost of forward and backward passes through the target model. For Pythia models, the cost of forward and backward passes is also proportional to pretraining compute because all Pythia model sizes were trained on a fixed dataset of 300B tokens (Biderman et al., 2023). Thus to compute the pretraining cost, we use  $C_{train} \approx (1.8 \times 10^{12})N$ , where  $N$  is the number of parameters in the model.

The exact number of pretraining tokens used for Qwen2.5 is not currently public, but we estimate it by combining the total number of tokens used for training Qwen2.5 models (18T) with the spread of tokens used for training Qwen2.5 (12T for Qwen2-0.5B, and 7T for all larger Qwen2 models). This gives 18T tokens for Qwen2.5-0.5B, and 10.5T tokens for all larger Qwen2.5 models.

### E.2 ADVERSARIAL TRAINING COMPUTE CALCULATION

The compute cost of adversarial training ( $C_{adv}$ ) consists of two parts: the training cost ( $C_{train}$ ), and the adversarial example search cost ( $C_{search}$ ); that is,  $C_{adv} = C_{train} + C_{search}$ .

We estimate both  $C_{train}$  and  $C_{search}$  empirically, by recording how many forward and backward passes are used in each round of adversarial training and applying the  $C_{forward} = 2ND$  and  $C_{backward} = 4ND$  approximations.

$C_{train}$  and  $C_{search}$  are not constant across rounds of adversarial training (see Appendix D): we train on more examples per round, resulting in  $C_{train}$  increasing; and we increase the strength of the attack used to search for adversarial examples, resulting in  $C_{search}$  increasing. Despite both increasing, the ratio  $C_{train}$  to  $C_{search}$  is not constant across rounds since they increase at different rates.

### E.3 ADVERSARIAL ATTACK COMPUTE CALCULATION

The estimated cost  $C_{search}$  represents the attack compute required to run the attack on the whole dataset, rather than the attack compute required to attack a single example. For Figure 7, we divide by the size of the dataset to get per-example compute, since we are interested in the question of how much compute an attacker would have to spend to have a chance of jailbreaking the model once.

## F MANUAL ADJUSTMENTS AND DISCREPANCIES IN ATTACK COMPUTE SCALING FIGURES

We add a manual adjustment to the attack FLOP estimates for IMDB and Spam in Figure 4. This is due to a bug in our code that occasionally resulted in an underestimation of FLOPs spent when evaluating across multiple GPUs. This only affected the 11.6B model.

As discussed in Appendix E.1, using the same number of attack iterations should use the same proportion of pretraining compute. Thus we corrected for this underestimation by scaling the FLOPs estimate for 11.6B so that the proportion of pretraining compute matched the other model sizes.

Another discrepancy in Figure 4 is the slight misalignment of the starting and ending points of each model on the  $x$ -axis. This is caused by the attacks being run on slightly different numbers of examples for each model size, since we start with a dataset of 200 examples and only attack those on which the model is successful.

## G ATTACK SUCCESS RATE INTERPOLATION

For Figure 7, we require an estimate of attack compute needed to achieve a given attack success rate. Given the discrete nature of the strength of our attacks, where increasing strength corresponds to performing another iteration of the attack, we will often not have a datapoint at the exact target attack success rate. To overcome this limitation, we perform linear interpolation between iterations to produce a smoothed estimate for the number of iterations—and thus the number of FLOPs as well—required to achieve the target attack success rate. Algorithm 3 lays out the details of the interpolation scheme.

---

### Algorithm 3 Attack Success Rate (ASR) Interpolation

---

**Require:**  $A = \{a_i\}$ , where  $a_i$  is ASR at iteration  $i \in [0, N]$

**Require:**  $t$ , target ASR

```

1:  $prev\_asr \leftarrow 0$ 
2: for  $i \in [0, \dots, N]$  do
3:    $curr\_asr \leftarrow a_i$ 
4:   if  $t = curr\_asr$  then
5:     return  $i$ 
6:   end if
7:   if  $prev\_asr < t < curr\_asr$  then
8:     return  $(i - 1) + \left( \frac{t - prev\_asr}{curr\_asr - prev\_asr} \right)$ 
9:   end if
10:   $prev\_asr \leftarrow curr\_asr$ 
11: end for
12: return None

```

---

## H ROBUSTNESS TRANSFER

**Does adversarial training protect against different attacks?** A concern we might have is that at deploy time, our model is subjected to attacks that were unknown (or did not exist) at train time. Can our adversarially trained model hope to defend against new attacks? We look for insight into this question by adversarially training our models on the RandomToken attack and then attacking with the GCG attack. Figure 28 shows models adversarially trained on RandomToken do perform better than undefended models, though the effect is quite weak. In this case, adversarial training appears to benefit smaller models more than large models, with the slope of improvement of small models being steeper. However, only one of the models across two tasks achieves a below 50% attack success rate, suggesting that the main result of this experiment is that adversarial training against RandomToken does not confer a meaningful amount of robustness against a much stronger attack like GCG. This result suggests that it is important to use a similar attack during adversarial training as expected at deployment. However, further work is needed to determine whether adversarial training on RandomToken fails because it is a different *kind* of attack, or simply because it is a much weaker attack.

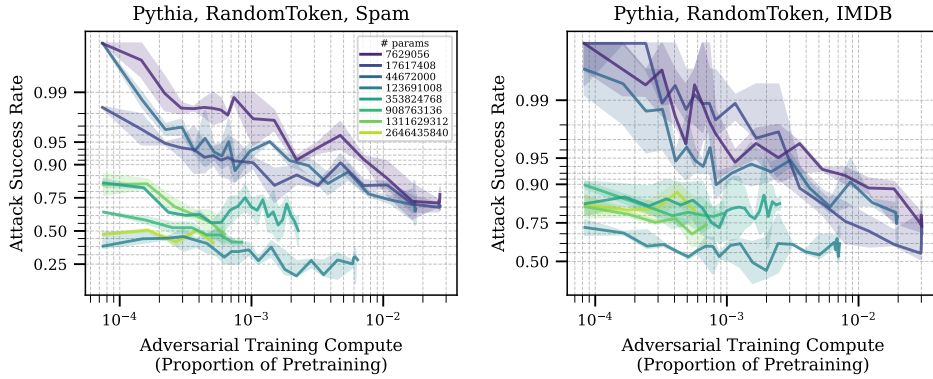

Figure 28: Transfer from adversarial training against 2048-iteration RandomToken to 128-iteration GCG on the Spam (**left**) and IMDB (**right**) tasks. All models become slightly more robust to GCG over the course of adversarial training using RandomToken. On both Spam and IMDB, larger models are more robust for the same proportion of adversarial training, but much of that is likely due to their better robustness before adversarial training starts. On both tasks, adversarial training with RandomToken appears to benefit smaller models more than larger models. However, this results should be taken with a grain of salt, as most models on both tasks do not surpass 50% attack success rate. As such, the main takeaway of this experiment is that there is only limited transfer of defense between adversarial training with RandomToken and evaluating with GCG.

Figure 28 shows that adversarial training against RandomToken is a weak defense against GCG, as discussed in more detail in Section 5.1.
